"Ohio" CYCLOPROPANE

To the medical profession the name Ohio on a cylinder of cyclopropane is doubly significant. "Ohio" not only represents highest purity quality and uniformity but is also a reminder that cyclopropane has gained favorable recognition as a dependable anesthetic through the pioneering and assistance supplied by "Ohio" laboratories and "Ohio" technicians in the development of cyclopropane for anesthesia.

One of the world's leading manufacturers of medical gases and administering equipment "Ohio Chemical" is constantly on the alert always ready to pioneer and to assist in new developments which will provide the medical profession with safe dependable anesthetics.

The Ohio Chemical & Mfg. Co., 1400 East Washington Ave., Madison 10, Wisconsin. Represented in Canada by Oxygen Company of Canada Limited, and Internationally by Airco Corporation (International), New York.

Ohio Medical Gases include Nitrous Oxide—Ethylene—Cyclopropane—Oxygen—Carbon Dioxide—Oxygen-Carbon Dioxide Mixtures—Helium—Helium-Oxygen Mixtures.

OHIO CHEMICAL MAKES

everything **FOR ADMINISTERING ANESTHETIC GASES**

• You will find Ohio Chemical a complete source of supply for all surgical anesthesia requirements, including gases and administering equipment • Heidbrink Kinet-o-meters meet all requirements of surgeon and anesthetist for the administration of the various anesthetic gases generally employed. Included in the 52 models described in the Heidbrink Surgical Anesthesia Catalog are mobile units of three types—cart, stand, cabinet—and portable apparatus weighing as little as 35 pounds • You cannot afford to decide upon anesthetic equipment without first having complete details of how "Ohio" can meet your needs. Write for Heidbrink Surgical Anesthesia Apparatus Catalog. For immediate detailed information, call our nearest branch sales office.

B-D NEEDLES

**assure these
ADVANTAGES**

A UNIQUE METHOD of sharpening and beveling, plus rigid inspection, assure varying uniformity of B-D needle points. Exclusive process of joining hub and cannula provides needles of consistently true bore from point to hub with every hub micrometer-gauged to assure perfect fit.

INTENSIVE and continuous research has provided the optimal compromise between stiffness and flexibility! hypodermic needles hyperchrome stainless steel stiff enough to hold a keen, durable point flexible enough to provide maximum resistance to breakage from bending and never a leaky joint.

BASIC DESIGN of B-D Needle point provides extra lateral cutting edges to insure relatively painless penetration. Solid sturdy construction protects against fish-hooks and burrs, while the velvet-smooth finish of the cannula contributes further to the utmost in patient comfort.

Sporicidal Too!

BARD PARKER FORMALDEHYDE GERMICIDE

Recognized authorities on surgical sterilization state emphatically that no disinfecting medium should be used in the operating room that is not capable of killing spores.

Compare the significant data outlining the potency of the various germicides

Sporulating Bacteria	10% Boiled Blood	Whole Blood
C. tetani	3 hours	3 hours
C. welchii	2 hours	2 hours
S. aureus	1 1/2 hours	1 1/2 hours
Vegetative Bacteria		
B. anthracis	5 min.	15 min.
E. coli	3 min.	15 min.
Strept. hemolyticus	2 min.	15 min.

Within a reasonably short period, practical for hospital purposes, this potent solution destroys pathogenic vegetative bacteria, spore formers and their spores.

True surgical disinfection is further accomplished without danger of rust or corrosive damage to sharp edged and other delicate surgical instruments, thus leaving their efficiency and life expectancy unimpaired.

In meeting ALL THREE exacting requirements of potency, practicability and protection, B-P Germicide provides desirable margin of safety for instrument disinfection.

Announcing

a time-saver for
the operating room

STERILJAR

Packaging of SCANLAN SUTURES

- ★ Always sterile
 - ★ Always visible
 - ★ Always ready for use
- IN THE OPERATING ROOM**

Steriljar packaging of Scanlan Sutures eliminates handling and sterilizing—the Steriljar serves as a germicidal container for the sutures right in the operating room, instantly available for use. All strands are sterilized in glass tubes, filled with sterile alcohol, and hermetically

sealed under conditions which retain sterility of the outside and the inside of tubes. Tubes are sealed in a germicidal solution within glass jar with plastic screw cap which has been rendered sterile. Suture tubes are packed 2 dozen or 3 dozen to a jar depending on size of tube.

STERILE TUBES

are ready for immediate use without further sterilizing or handling. This reduces tube breakage, saves nurses time.

DEEP IMMERSION

Sufficient alcohol above the Sterile Tubes assures complete germicidal coverage until almost all sutures are removed. No additional germicide to buy.

STERILJAR

complete with non-metallic cover serves permanent storage jar for the operating room—saves buying and sterilizing ordinary storage jars.

VISIBILITY

The deep glass of which Steriljar is made keeps tubes always visible for inspection and quick counting.

Scanlan Sutures are packed 2 dozen or 3 dozen to a jar, depending on size of tube.

SEALED SCREW CAP

Plastic screw cap is sealed on—guarantees that both sutures and jar are sterile when packed. Steriljar is tested and proved.

**Why
B-D NEEDLES
are always
UNIFORM**

No matter what the gauge or size, uniformity is an outstanding characteristic of all B-D NEEDLES.

Hyperchrome stainless steel tubing provides the optimal compromise in a needle stiff enough to hold a point without fish hooking and flexible enough to withstand maximum bending without breaking.

From point to junction of cannula and hub, B-D NEEDLES hold practically true bore. Hubs are micrometer gauged to assure uniform fit. Basic design of B-D needle points provides extra lateral cutting edges to achieve relatively painless penetration. Cannula and hub are joined by unique application of parallel longitudinal pressure to insure against leakage and against crimping of cannula. Buffing and finishing produce a velvet-smooth surface and inspection is rigidly maintained throughout every phase of manufacture.

B-D NEEDLES

assure these
ADVANTAGES

A UNIQUE METHOD of sharpening and bevelling, plus rigid inspection assure unvarying uniformity of B-D needle points. An exclusive process of joining hub and cannula provides needles of consistently true bore, from point to hub with every hub micrometer gauged to insure perfect fit.

INTENSIVE and continuous research has provided the optimal compromise between stiffness and flexibility in hypodermic needles. hyperchrome stainless steel hard enough to hold a keen, durable point, flexible enough to provide maximum resistance to breakage from bending, never a leaky joint.

BASIC DESIGN of B-D Needle point provides extra lateral cutting edges to insure relatively painless penetration. Solid, sturdy construction minimizes fish-hooks while the velvet-smooth finish of the cannula contributes further to the utmost in patient comfort.

How B-D NEEDLES assure SAFETY

LONG AND INTENSIVE B-D RESEARCH has developed an extremely fine compromise between hardness and flexibility in steel tubing. This B-D needle tubing holds a keen point, yet bends safely without breaking. Cannula and hub are joined securely by parallel longitudinal pressure to prevent leakage to eliminate pinching of cannula to insure practically true bore from point to hub.

BASIC DESIGN of B-D needle points provides extra lateral cutting edges to achieve relatively painless penetration. Micrometer gauged hubs insure proper fit on any B-D syringe tip, and hinder popping off of needle during injection.

SUCH RIGID MANUFACTURING DETAILS afford greatest safety to the operator greatest comfort to the patient.

APOCRINE TISSUE, CHRONIC CYSTIC MASTITIS AND SWEAT GLAND CARCINOMA OF THE BREAST

JOHN F HIGGINSON M.D. and JOHN R McDONALD M.D., Rochester Minnesota

SINCE "pale epithelium" was first described, it has been the object of numerous pathologic and experimental studies. It has been considered variously as evidence of degeneration, carcinoma, precancerous tissue, evidence of atavism, metaplasia, heteroplasia and alloplasia, a variant of normal breast tissue, sweat gland tissue, and finally, and most important, apocrine skin gland tissue.

It has been found by some workers in the pithers of the normal breast and by fewer

Abridgment of thesis submitted by Dr. Higginson to the Faculty of the Graduate School of the University of Minnesota. Partial fulfillment of the requirements for the degree of Master of Science in Surgery.

From the Division of Surgery, Mayo Foundation, and the Section on Surgical Pathology, Mayo Clinic.

workers in the depths of the normal breast proper. It has been related etiologically to carcinoma of the breast and especially to chronic cystic mastitis; it has also been listed as an accompaniment of these and other lesions of the breast. Many papers have been written concerning the embryology of the breast and other cutaneous glands, especially the sweat glands, which tend to show a common origin or relationship or none at all. Morphologic studies have been reported; clinical observations have been recorded; and experiments have been performed which show a relationship of "pale epithelium" in the breast to sweat glands, to various pathologic and physiologic body states and to various hormonal imbalances.

Fig. 1. Axillary specimen of skin showing apocrine glands in secretory and resting stages. The eosinophilia is apparent. Also visible are a sebaceous gland and an eccrine (true sweat) gland. Hematoxylin and eosin $\times 33$.

Fig. 2. Same tissue as in Figure 1. View of tall columnar epithelium which contains red-staining and brown pigment granules. Myoepithelial cells can be seen in cross section on the left and in longitudinal section above on the right. Hematoxylin and eosin $\times 280$.

Fig. 3. Section from a breast removed for carcinoma (malignant tissue not shown here). The pale epithelium is seen in and as part of a lobule of the breast surrounded by "normal" or usual mammary tissue. No cystic change is present. Hematoxylin and eosin $\times 45$.

Fig. 4. Section from a breast removed for extensive chronic cystic mastitis. Note cystic change in acini and papillary formation of the pale epithelium. Hematoxylin and eosin $\times 17$.

Fig. 5. Section from a breast removed for chronic cystic mastitis. Note the eosinophilic granules and the fewer brownish granules. Hematoxylin and eosin $\times 25$. Compare with Figure 2.

Fig. 6. Section from a breast removed for carcinoma (malignant tissue not shown here). Note brown yellow pigment granules (in unusual abundance in this section), and also a few fat droplets. Myoepithelial cells in tangential and longitudinal section. Hematoxylin and eosin $\times 235$.

Fig. 7. Section from a breast removed for carcinoma (malignant tissue not shown here). Note direct continuity between apocrine sweat gland type of tissue ("pale epithelium") and usual or "normal" mammary tissue. Hematoxylin and eosin $\times 130$.

Fig. 8. Section from a breast removed for carcinoma (malignant tissue not shown here). Pale epithelium shows hyperplasia. Enlarged, hyperchromatic nuclei contain enlarged, hyperchromatic, often multiple nucleoli. Two, three, and four nucleoli can be seen in some instances. Hematoxylin and eosin $\times 325$.

Fig. 9. Section from a breast removed for carcinoma. Malignant cells are visible. The morphologic and especially the staining characteristics are similar to those of "pale epithelium" except for the obvious signs of malignancy. These cells look strikingly different from those in the commoner carcinoma of breast. Hematoxylin and eosin $\times 45$.

The purpose of the study recorded herein was to attempt to establish the status of the so called pale epithelium in the breast.

The frequent finding of this tissue in routine sections of surgically resected breasts aroused curiosity concerning it and moreover the term "Schimmelbusch hyperplasia, which is used to designate this tissue was thought, and later found to be incorrect. In addition the similarity of appearance of this 'pale epithelium and the epithelium of apocrine sweat glands elsewhere in the body seemed to indicate a relationship not commonly discussed or understood.

For the purpose of this study a review of the literature was undertaken covering the embryology physiology morphology and pathology of the cutaneous glands particularly the mammary and other apocrine skin glands.

In addition 97 unselected surgically removed breasts were studied to redetermine the incidence of pale epithelium in pathologic breasts the histologic picture presented by this tissue and the degree of similarity in structure and staining reaction of this tissue to that of apocrine skin gland tissue such as is found in the axilla. For the latter comparison, postmortem specimens of axillary skin were obtained at random from 6 subjects of varying sex and age in these cases death had resulted from various illnesses but in none were there lesions of the breast. There are three types of cutaneous glands in the human being namely (1) the holocrine (sebaceous) glands, (2) the eccrine (sweat) glands, and (3) the apocrine glands. The last mentioned consist of odoriferous or accessory sex glands which are found in the axilla in the groin and genital region and in the perianal region the ceruminous glands Moll's glands and the mammary glands.

Apocrine glands are not sweat glands in any manner as we understand and use the term

in the breast of tissue resembling, or identical with, other apocrine gland tissue such as is found in the axilla.

This study confirms those of others who have remarked on the morphologic and staining similarity and lends support to the argument that there is a logical basis for the histologic appearance of certain lesions of the breast such as the much mooted so called sweat-gland carcinoma of the breast.

REVIEW OF LITERATURE

Robin and Horner (18 19) emphasized sharply the difference between the 2 types of sweat glands in man and working individually they noted that in the axilla these glands lay in a definitely localized group but that they also could be found in the inguinal fold. Both men noted that there seemed to be a distinct and prominent odor emitted from these glands. Horner terming them the odoriferous glands, and both men observed that the glands were macroscopic and appeared to have a pink or reddish color. Schiefferdecker offered the following classification of the cutaneous glands.

- 1 Holocrine glands (sebaceous gland or hair follicle gland)

- 2 Merocrine glands

- a Merocrine-apocrine glands (large sweat glands in human beings, the glands of the hairy skin of most mammals, and the "milk glands and mammary glands)

- b Merocrine-eccrine glands (small sweat glands in human beings the glands in the soles of the paws of the cat and the dog in the snout of the swine, and in small numbers in the skin of some apes and so forth)

He made the point that actually the apocrine glands are not real or true cutaneous glands but an entirely special type of gland which is found in various parts of the body. In mammals these glands can and do occur in the skin and so in these animals they become cutaneous glands. In this way they fortuitously become neighbors of the eccrine glands.

between the "sweat" glands and the milk glands. Rein in 1882 noticed the earliest trace of the anlage of the breast in the human embryo of 24 millimeters (6 to 7 weeks old) and stated that he considered the Montgomery glands to be miniature copies of the mammae but at a slightly earlier stage of development. Benda (1, 2) considered the deeper portion of the Montgomery gland to be of the apocrine "sweat" gland type. Brouha in 1905 correlated the human areola with the peripheral section of the primitive mammalian gland field. Brouha and later Schiefferdecker stated that this fact easily explained the participation of the areolar glands in the secretion by the milk gland at the time of birth (with s milk) and also the occasionally seen phenomenon of secretion of milk by these glands which earlier (in lower animals) were regularly employed in the nourishment of the newborn. They stated that, accordingly in human beings there can be found in the milk glands and in the areolae all gradual changes or transitions of the apocrine glands from the central large milk gland through the smaller accessory milk glands to the usual apocrine glands.

Richter found iron in all of the apocrine glands of men and animals that he examined and he considered its presence a general earmark. He stated also that these glands secreted cholesterol, an observation which had been made previously by Walter (50) in 1924.

Way and Memmesheimer agreed with Herzenberg and others that the apocrine glands deserve consideration as accessory sexual glands. They stated that there seemed to be a definite relation between cellular activity and the amounts of cholesterol and hemofuscin present, and they found these substances as well as hemosiderin in their specimens.

Kölliker (21) and Talke (46, 47) were among the first to mention and describe muscular fiber cells in the sweat glands.

Sheldon in 1941 found myoepithelium present in breasts eccrine and apocrine sweat glands, Moll's glands and the ceruminous glands of the ear. Similar contractile epithelial elements called "basket" cells are found in the salivary and lacrimal glands as noted by Loeb. Kölliker (22) in 1889 described the myoepi-

thelium as forming the outer of two layers of cells within the basement membrane. This myoepithelium is considered to be ectodermal in origin (Kölliker, 22, von Eggeling, Schiefferdecker, Hamperl, Sheldon, Kuzma, and others).

In 1941 Suzuki in discussing carcinoma of the sweat glands stated that one class which he called 'carcinoma sudoripara cysticum papilliferum' should include the sweat gland adenocarcinomas of the vulva, carcinomas of apocrine glands elsewhere such as von Winkler's case (ceruminous gland) and Salzmann's case (Moll's glands) and also so called sweat gland carcinomas of the breast. Gates, Warren, and Warvi stated that the histogenetic relationship had not been established between apocrine glands and the cells of some types of carcinoma of the breast as, in their opinion, all of the cutaneous appendages, including the mammary gland, derive from the primitive surface epithelium independently.

In 1937 Weiner suggested that Paget's disease of the skin is the result of intraepidermal metastasis from an underlying carcinoma of apocrine sweat glands and he noted that the lesion in all cases of extramammary Paget's disease occurs in sites where apocrine glands are found and that mammary glands are also modified apocrine glands.

Krompecher (24) expressed the thought that small cysts lined with 'pale epithelium' could be found in normal as well as in cystic and cancerous breasts; he found them in all but 1 of 23 cases of cystic disease of the breast. He offered two possible explanations for the occurrence in the breast of this 'pale epithelium': (1) that genuine coiled sweat glands of the skin in the form of aberrant buds in breast tissue occurred and underwent cystic enlargement and (2) that the breasts since they are phylogenetically derived from 'sweat' glands in the course of their development by steps, remained behind in part, at a phylogenetically earlier stage nearer that of the 'sweat' glands. He considered the latter explanation more likely because he never saw in the breast typical quite normal sweat glands but instead saw sweat gland cysts which indicated to him a defective differentiation and favored an atavistic phenomenon.

In 1924 Krompecher (25) stated that the similarity between cysts of "pale epithelium" in the breast and cysts of the axillary sweat glands is so striking that they must be identical. He noted the unusual size of the cells their dublike appearance when distended and their firm occasionally granular or finely vacuolated cytoplasm which stained yellow with van Gieson's stain and reddish with eosin.

Ewing stated that true sweat glands are not present in the breast but that in many cases there is in the breast a type of gland which we speak of as sweat glands. I feel that this is a special form of gland structure in the breast which develops in a certain type of subject notably those with an oily skin and many sweat glands in other parts of the body. Some men think there is a transition between the ordinary acini and the sweat gland. He estimated that 25 per cent of mammary carcinomas arise from sweat glands distributed throughout the breast but mostly along the margins beneath the skin and in the axillary region. He described one form of cyst in chronic cystic mastitis as developing from the sweat glands in the breast.

Lee Pack, and Scharnagel agreed with von Eggeling's statement that the mammary and sweat glands are homologous structures which develop from a common primitive tubular type of epidermal gland. They stated their belief that sweat glands (apocrine) are normally present in every breast where they anastomose with and empty their secretions into the interlobular lacteal ducts. They said it is unimportant to determine whether the 'pale epithelium' is anomalous embryonal normal or degenerative tissue their major premise being that the breast is a modified sweat gland and that the appearance of sweat gland tubules and cysts in the breast is a logical occurrence regardless of the mode of origin. They considered it significant that the anatomic and staining characteristics of this tissue remained throughout all the transitional phases of normal sweat gland tubule cyst intracystic papilloma adenoma and carcinoma.

In the same year Logie reported 'pale epithelium' in 60 per cent of 330 malignant and nonmalignant tumors of the breast.

In January 1946 Foote and Stewart recognized sweat gland carcinoma as constituting 1 per cent of carcinomas of the breast and stated that it should properly be called apocrine sweat gland carcinoma. They expressed the belief that the cells of the ducts or lobules undergo apocrine metaplasia, and they found convincing transitions ranging from typical apocrine epithelium to apocrine epithelium in atypical hyperplasia to intraductal apocrine sweat gland carcinoma and, finally to infiltrating carcinoma made up of apocrine-like cells.

SCHIMMELBUSCH HYPERPLASIA

As previously noted, 'pale epithelium' has been described in many pathologic specimens from the breast especially in those which have been the seat of chronic cystic mastitis. It has been the custom at the Mayo Clinic, perhaps elsewhere also to describe the last mentioned specimens with the diagnostic appellation chronic cystic mastitis with areas of Schimmelbusch hyperplasia." The latter portion of this term we consider incorrect.

Although Moullin in 1881 and Dreyfuss in 1888 had mentioned the pale structures, Schimmelbusch if he noted such tissue at all, made no specific mention of it. Under the title cystadenoma of the breast. In 1890 (40) and again in 1892 (41) he gave his description of what he said had been described previously by Reclus (33-34) as *maladie kystique des mamelles*. He stated that he thought it should be called cystadenoma," because in addition to the cyst formation there was growth or proliferation of the glandular tissue.

With hindsight it is possible to suppose that Schimmelbusch did see what we now call "pale epithelium" and that he described it as an intrinsic part of chronic cystic mastitis. However judging from his description one can merely say that he never described pale epithelium.

In the years that followed other men used the term Schimmelbusch's disease synonymously with cystic disease of the breast "mastopathia cystica" or chronic cystic mastitis, and so forth in their descriptions and discussions of 'pale epithelium'. Most of these workers in correlating the various de-

scriptions of the broad clinical and pathologic entity known most popularly as "chronic cystic mastitis," placed the phase described by Schimmelbusch at the upper, or more hyperplastic, end. This probably strengthened further the misconception concerning what Schimmelbusch saw and described (4 6 10 23 25).

Cheatle and Cutler in 1931 Cutler in 193 and Cheatle in 1935 stated that what Schimmelbusch described, they considered the neoplastic stage of cystiferous desquamative epithelial hyperplasia, and the pictures of the papillary epithelium shown by them as neoplasia are pictures of pale epithelium.

It thus may well be that Schimmelbusch actually saw what we now know as pale epithelium. It would seem likely that he had seen it, since it is so commonly present in chronic cystic mastitis. However we have only his descriptions from which to judge, and he does not mention pale structures or 'pale epithelium' though he does mention papillary epithelial proliferations.

The use of the term 'Schimmelbusch hyperplasia' at the clinic has been largely a matter of convenience and has been well understood. It was also recognized by most of the pathologists as incorrect, even before this study was begun in 1940. There is little doubt in the minds of most of these men that this "pale epithelium" regardless of its mode of origin is apocrine tissue and should be so designated. Some of the more recent contributions to the literature from other institutions indicate that this thought is by no means provincially unique.

PRESENT STUDY

Material. Six specimens of axillary skin were removed without selection simply in order that the scent glands in human beings might be studied (Figs 1 and 2).

Ninety-seven breasts were received in the surgical pathology laboratory directly from the operating rooms without any plan of selection except to accept whatever came in.

It had been noted previously by one of us (J. R. McD.) that there were tiny pinkish bits of tissue and equally tiny, bluish frequently macroscopically cystic bits of tissue to be found in most breast specimens and that

TABLE 1 — INCIDENCE OF PALE EPITHELIUM

Diagnosis	Breasts				
	Total	With pale epithelium			
		Number	Percent	Macroscopic pink or bluish areas	
				Number	Percent

Fibrous trophic mastitis					
Total	97	72	73.2	34	71.0

these bits of tissue usually were composed of pale epithelium (Figs 3, 4, 5, 6, and 7). Accordingly these were looked for and, if found, were removed in small blocks for sectioning and staining if none were found then blocks were cut at random from the breast. All specimen blocks were cut from the depths of the breast proper, the subcutaneous areas being avoided.

Pale epithelium was found in three-fourths of all the breasts examined, and in three-fourths of the instances in which it was present it could be found with the naked eye (Table 1). It should be stated that the pink and bluish areas mentioned varied from 0.5 millimeter to 3 or 4 millimeters in diameter. Larger areas (always bluish) were not used, because the cystic dilatation and expansion had flattened the epithelium. The term "blue-domed cyst" has been applied by at least one man to these bluish structures, but since this term has been used in a grossly descriptive way—not implying any specific tissue but merely a gross, refractive phenomenon and a lack of malignancy—I feel that this term would be misleading if used to indicate these pale epithelial cysts (Table II).

Intracellular granules. The mere noting of intracellular granules in the pale epithelium was not difficult. The presence of granules of one kind or another was open to argument only in those instances in which the epitheli-

TABLE II — INCIDENCE OF CYSTIC CHANGE IN PALE EPITHELIUM ON MICROSCOPIC EXAMINATION

um was moderately or considerably flattened as a result of cystic dilatation of the epithelial glands. As a rule the granules were quite obvious. Sometimes they stood out in a most striking manner showing extremely marked eosinophilia (Table III). There were several types of granules. The great majority were eosinophilic granules large or very fine which stood out even against the smoothly eosinophilic cytoplasm (Fig 5). Then there were yellowish or brownish granules—present in only a few of the cells of any particular acinus of pale epithelium—which were even more readily visible in the sections stained with Berlin blue but which were apparently untouched by either of the two stains, Berlin blue or hematoxylin and eosin (Figs. 5 and 6).

Another type of granule was a very fine one—also not present in all the cells—which gave a fat reaction with the sudan III stain in the few such slides which were made. There were noted also some fat droplets of varying size in a few of the cells (Fig 6).

Finally there was the type of granule which gave a positive reaction to the Berlin blue stain. Whether this one was identical with one of the previously mentioned types or represented a different metabolic stage of one of them was not established in this study. Certainly when numerous markedly eosinophilic granules were seen in the section stained with hematoxylin and eosin there was no correspondingly marked iron reaction in the section stained with Berlin blue. While there were usually a few cells found which contained a few or many granules giving a positive reac-

tion to the stain for iron there was not a universally present iron reaction in all the cells. There was extreme variation in the iron reaction not only from cell to cell but from gland to gland or acinus to acinus, in the same slide. Although in a few instances there was a suspicion of a positive iron reaction in the cells of some of the regular mammary epithelium this was not definite enough to deny the pale epithelium the uniqueness of this reaction.

Hyperplasia and papillary formation. Although papillary formation seemed to indicate growth activity or even overactivity it was sometimes noted when there was no evidence of hyperplasia. Usually however hyperplasia and papillary formation were seen together and if hyperplasia were present papillary formation was always present also (Table IV).

Hyperplasia was adjudged present principally on the basis of individual changes, differences and appearances of cells and not merely because of an increase in the number of cells. If the nuclei of some of the pale epithelial cells were one and a half to two times as large as the nuclei usually seen and if they were hyperchromatic and contained multiple, large, hyperchromatic nucleoli or mitotic figures, then the cells containing them were considered hyperplastic (Fig 8).

The myoepithelium. At first it was somewhat difficult to be certain about the myoepithelial cells (Fig 6) but as more slides were examined and some very definite examples were seen, then the less obvious cells became more apparent. These cells are easily confused

with cells in the capillary walls lying immediately nearby, outside the basement membrane but this confusion, noted in the literature would seem more often to be due to cells, possibly reticular cells, which are seen actually in the basement membrane which are very similar to the cells in capillary walls. The myoepithelial cells lie directly beneath the epithelium, above or on the basement membrane.

The myoepithelial cells are long spindle shaped and not too numerous or closely packed in the unchanged gland or acinus. They seem as a rule to be thicker at the middle than do the usual reticular cells or the cells of the capillary walls and when they apparently participate in hyperplastic activity they multiply in to a definite layer and appear more like epithelial cells than the smooth muscle cells which they usually resemble.

Age There was no great difference in average age between the group of patients whose breasts did contain pale epithelium and the group of patients whose breasts did not contain pale epithelium. The respective average ages were 47 and 49 years.

Relation of pale epithelium and papillary formation to the menopause Sixty five per cent of the specimens of breast with pale epithelium which showed papillary formation or papillary formation with hyperplasia, came from women past the menopause or in the midst of the menopause. This does not imply necessarily that the menopause, with its hormonal changes is solely responsible for the occurrence of pale epithelium but it might suggest that the menopausal and postmenopausal hormonal imbalances may be related to the histologic evidences of growth activity. Speert's experimental work with estrogenic hormones is very pertinent in these respects.

COMMENT AND SUMMARY

There is little doubt in our minds that the pale epithelium discussed in this study found in breasts and illustrated in Figures 3, 4, 5, 6, 7 and 8 is actually apocrine glandular tissue identical with the axillary apocrine scent glands (Figs 1 and 2). This is not an original concept and this study has not conclusively proved the identity. Truly conclusive proof

TABLE IV — INCIDENCE OF PAPILLARY FORMATION AND HYPERPLASIA IN BREASTS WITH PALE EPITHELIUM

Diagnosis	Breasts with pale epithelium				
	Total	Papillary formation		Hyperplasia	
		Number	Per cent	Number	Per cent
Carcinoma	41	20	48.8	13	31.7
Chronic cystic mastitis	20	9	45	8	40.0
Chronic fibrous mastitis	3		33.3	0	
Intraductal papilloma	6		33.3		33.3
Chronic mastiti	3		66.7	1	33.3
Total	72	34	46.6	24	33.3

would rest on a cellular biochemical study with identification of secretions from the tissue. Nevertheless it would seem justifiable to consider this tissue to be apocrine scent gland tissue on the basis of similar staining and morphologic characteristics.

We have refrained except where unavoidable for clarity's sake from referring to this pale epithelium as sweat glands, sweat gland epithelium, apocrine sweat glands or by any other term which is suggestive of sweat or sweat glands. Apocrine glands generally the scent glands in particular are not sweat glands as Schiefferdecker showed. The latter term has been inappropriately and inaccurately applied to them because they lie in the skin and morphologically are coiled glands. Their function in man has no bearing on the control of body temperature and they do not excrete large amounts of water and metabolites such as urea, instead they elaborate a definite substance or secretion which itself has a role in the primitive animal economy.

The breast is an apocrine gland on the basis of its mode of secretion that is all that the term "apocrine" indicates. The breast is also a highly specialized modification of a certain primitive cutaneous gland the latter being likewise parent to the scent gland (also an apocrine gland). Neither of these glands 'sweats' in the manner of the epicrine or eccrine or true sweat gland. They secrete rather than excrete a definitely elaborated substance, the elaboration occurring in the cells of the glands. The excretory function of the eccrine gland,

on the other hand, is closely akin to that of the renal tubule

The mere anatomic location of the scent glands that is in the skin as well as some of their morphologic characteristics led quite naturally to the inaccurate appellations sweat glands then large sweat glands and more recently apocrine sweat glands. In the same way the breast is referred to as a modified sweat gland though nobody considers that the breast sweats or that its secretion is sweat

The term apocrine glands when applied to the breast, the scent glands the ceruminous glands and so forth is accurate as far as it goes but it merely denotes a group of glands distinctive as to their method of secretion. Since these glands have also their origin in common the term apocrine skin glands might temporarily suffice as an over all group name

The scent glands could well be known in addition and separately as the scent glands or odoriferous glands or accessory sexual glands. Such terms have been suggested as mentioned previously and they are as fully individual and distinctive as the term mammary gland or the term ceruminous gland. The pale epithelial structures encountered in the breast might then be referred to as scent gland tissue in the breast or accessory sexual gland tissue in the breast. There is of course some redundancy here since the breast might very well exhibit and contain such pale epithelium as an expected thing inasmuch as the breast is a modification of the same primitive gland from which the scent gland is derived and inasmuch as the scent gland in its characteristics does not seem to be far removed or greatly modified from the primitive glands. Hence such epithelium might be considered the primitive epithelium and its presence in the breast merely evidence of a reversal in part even though the stimulus for such reversion might be a hormonal one

Even more to be expected perhaps, is the finding of this pale epithelium in supernumerary or accessory breasts and especially in so-called aberrant breasts. As mentioned in the review of the literature breastlike structures have been described on most parts of the body including the extremities. There is no doubt about the finding of true breast tissue

In the supernumerary or accessory breasts, but this does not necessarily indicate that all of the structures described as breasts or breastlike structures or aberrant breasts actually are composed of breast tissue. Obviously many of these structures are outside the embryologic milk line and may well be and probably are hypertrophied apocrine glands of the more primitive or scent gland type. Even those which are in the milk line and are more breastlike may well be of the primitive type of apocrine gland but are simply further along in the differentiation to breasts as required of such glands lying in the milk-line. As H. E. Walter stated in 1903 no known mammal living or extinct has, or had, as many mammae as there are recorded sites for accessory breasts, so called. The only alternative explanation is that these aberrant breasts are really hypertrophied primitive apocrine glands, which being outside the milk line and therefore lacking the undefined embryologic and phylogenetic stimulus for specific organ formation that is breast formation are unable to form true breasts. The gross caricature therefore is to be expected, and the misinterpretation there by is easily explained.

As already mentioned we consider the pale epithelium to be a relatively normal finding in the breast. If we consider the breast as a stable organ exhibiting little change except slowly and over long periods of time, then the occurrence of somewhat primitive epithelium, that is the pale epithelium could be considered definitely abnormal. However as has been remarked by many workers (Ingleby and others) the breast is not normal. It is not static but it is a rapidly frequently changing organ which is subject to many and diverse influences. Monthly it goes through a series of elaborate growth changes in preparation for a specific function. In view of these facts the finding of pale epithelium that is the presumptive primitive epithelium not only does not seem extraordinary but seems to be normal. This pale epithelium in the breast, however might be explained somewhat differently. Its function may be to impart the characteristic mammalian racial, and individual odor or odors to the milk a hangover in the human being from more primitive evolutionary stages.

It is our impression that pale epithelium could be found in every breast if diligently sought after. Although arriving at an entirely different conclusion about it, Dawson stated that the pale structures are to be expected in practically every pathologic and cystic condition of the breast malignant or not. She found such structures in 116 of 120 breasts which were the sites of malignant lesions and in all of 48 cystic breasts. Prym, and Berka have ever reported pale epithelium in otherwise normal breasts, and it is our opinion that it can be found in any and all female breasts after the age of puberty. That it seems to be increased in quantity in breasts which are the sites of certain pathologic conditions such as carcinoma and chronic cystic mastitis seems to us further evidence of a hormonal relationship or dependency. The question of the possession of carcinogenic properties by hormones especially the sexual hormones is well known and is frequently discussed. If one assumes an excess or increased potency of certain ovarian hormones as a possible explanation or cause of chronic cystic mastitis and carcinoma of the breast, there is no reason to deny the assumption that side effects occur such as an increase in the amount of pale epithelium in the breast. That pale epithelium will appear in response to the action of estrogenic hormones for instance would seem to be strongly suggested by Speert's experimental work. This may account for the easily noted high incidence of pale epithelium in breasts which are the sites of chronic cystic mastitis for instance. This is not an original concept other men having noted something of a relationship between chronic cystic mastitis and adnexal disease (48). The pituitary hormonal fractions undoubtedly play some direct or indirect role in this relationship and are under wide discussion in the literature.

Lee Pack and Scharnagel have noted much more pale epithelium in the breasts of patients with oily skin and much body hair than in breasts of persons with less oily skin and less body hair. This again would indicate a pituitary-gonadal relationship which is necessarily hormonal in character. Semb found an increased incidence of chronic cystic mastitis in nulliparas but made no study of the inci-

dence of pale epithelium though, judging from the present study as well as others mentioned the incidence should have been very high. The most obvious conclusion from all this would be that estrogenic hormone has direct control over the occurrence of pale epithelium in the breast but the involved endocrine gland relationship in the human being would make this a risky conclusion without further experimental work.

In so far as chronic cystic mastitis is concerned there is no doubt that the cystic changes occurring in the pale epithelium contribute to the grossly cystic character of the pathologic picture and indeed some men consider the disease one solely of pale epithelial structures (4). In view of the frequent association of chronic cystic mastitis with carcinoma of the breast (30), it is even possible to explain on this basis the reported findings (our own also) of a relatively high incidence of pale epithelium in carcinomatous breasts.

The question that a malignant lesion the so called sweat gland carcinoma of the breast may arise from the pale epithelium is still debated. From a practical standpoint the tissue of origin of a carcinoma of the breast is of little significance to the patient since low grade carcinomas arising from the usual or normal mammary tissue have metastasized and killed and since high grade carcinomas similarly arising have apparently been cured. It would be of significance to determine the tissue of origin only if it were known or could be shown that carcinomas arising from pale epithelium were usually low grade slow growing and slow to spread or were usually high grade fast growing and fast spreading. This would then be of prognostic significance and value. However as remarked by others (14) various gradations have been noted as occurs among carcinomas arising from the usual or normal mammary tissue. This has been our experience. Of the 54 carcinomatous breasts which we examined there were 8 malignant lesions (15 per cent) which *might* be termed so called sweat gland carcinoma or more properly scent gland carcinoma of the breast (Fig 9). However, the argument as to the distinction or separation of such carcinomas of the breast seems unnecessary and superfluous in

on the other hand is closely akin to that of the renal tubule

The mere anatomic location of the scent glands, that is, in the skin as well as some of their morphologic characteristics, led quite naturally to the inaccurate appellations sweat glands then large sweat glands and more recently apocrine sweat glands. In the same way the breast is referred to as a modified sweat gland though nobody considers that the breast sweats or that its secretion is sweat.

The term apocrine glands when applied to the breast the scent glands, the ceruminous glands and so forth is accurate as far as it goes, but it merely denotes a group of glands distinctive as to their method of secretion. Since these glands have also their origin in common the term apocrine skin glands might temporarily suffice as an over all group name.

The scent glands could well be known in addition and separately as the scent glands or odoriferous glands or accessory sexual glands. Such terms have been suggested as mentioned previously and they are as fully individual and distinctive as the term mammary gland, or the term ceruminous gland. The pale epithelial structures encountered in the breast might then be referred to as scent gland tissue in the breast, or accessory sexual gland tissue in the breast. There is of course some redundancy here since the breast might very well exhibit and contain such pale epithelium as an expected thing inasmuch as the breast is a modification of the same primitive gland from which the scent gland is derived and inasmuch as the scent gland in its characteristics, does not seem to be far removed or greatly modified, from the primitive glands. Hence such epithelium might be considered the primitive epithelium and its presence in the breast merely evidence of a reversion in part even though the stimulus for such reversion might be a hormonal one.

Even more to be expected perhaps is the finding of this pale epithelium in supernumerary or accessory breasts and especially in so-called aberrant breasts. As mentioned in the review of the literature breastlike structures have been described on most parts of the body including the extremities. There is no doubt about the finding of true breast tissue

in the supernumerary or accessory breasts but this does not necessarily indicate that all of the structures described as breasts or breastlike structures or aberrant breasts actually are composed of breast tissue. Obviously many of these structures are outside the embryologic milk-line and may well be and probably are, hypertrophied apocrine glands of the more primitive or scent gland type. Even those which are in the milk line and are more breastlike may well be of the primitive type of apocrine gland but are simply further along in the differentiation to breasts as required of such glands lying in the milk line. As H. E. Walter stated in 1903 no known mammal living or extinct has, or had as many mammae as there are recorded sites for accessory breasts, so called. The only alternative explanation is that these aberrant breasts are really hypertrophied primitive apocrine glands, which being outside the milk line and therefore lacking the undefined embryologic and phylogenetic stimulus for specific organ formation that is breast formation are unable to form true breasts. The gross caricature therefore is to be expected and the misinterpretation thereby is easily explained.

As already mentioned we consider the pale epithelium to be a relatively normal finding in the breast. If we consider the breast as a stable organ exhibiting little change except slowly and over long periods of time then the occurrence of somewhat primitive epithelium, that is, the pale epithelium could be considered definitely abnormal. However as has been remarked by many workers (Ingleby and others) the breast is not normal. Monthly it goes through a series of elaborate growth changes in preparation for a specific function. In view of these facts the finding of pale epithelium, that is, the presumptive primitive epithelium not only does not seem extraordinary but seems to be normal. This pale epithelium in the breast, however might be explained somewhat differently. Its function may be to impart the characteristic mammalian racial and individual odor or odors to the milk a hangover in the human being from more primitive evolutionary stages.

VAGINAL OPERATIONS FOR CYSTOCELE, PROLAPSE OF THE UTERUS, AND STRESS INCONTINENCE

WILFRED SHAW M.A. M.D. (Cantab.) F.R.C.S. (Eng.) F.R.C.O.G., London, England

PERHAPS the most important factor in the etiology of prolapse is a loss of tone of the plain muscle tissue of the endopelvic fascia and it is for this reason that the worst cases are seen in women of menopausal age or in postmenopausal patients. Other important factors are loss of tone of the levator ani muscles themselves and separation of the two levator muscles where they come together in the region of the perineal body as the result of lacerations during childbirth. The work of Halban and Tandler (2, 6) and Amreich (4) particularly has emphasized the distinction between the endopelvic fascia and the pelvic fascia which covers the levator ani and obturator internus muscles. Although it may be difficult and sometimes impossible to define the endopelvic fascial layers by histology (Goff) they can be demonstrated quite easily at operation. More over for successful plastic surgery in the treatment of prolapse a detailed knowledge of the anatomy of the different layers is required. It is the purpose of this paper to call attention to certain anatomical details and to show how this knowledge can be applied to vaginal plastic surgery.

VAGINAL OPERATIONS ANATOMY OF THE VAGINAL WALLS

In the anterior vaginal wall immediately above the level of the urethral meatus and the anterior termination of the hymen is a transverse groove which I have called the submeatal sulcus (Fig. 1, 5). I believe that the sulcus indicates the position of the urogenital diaphragm. In the anterior vaginal wall about 3 centimeters above this level is a second groove which I have called the transverse sulcus of the anterior vaginal wall. This sulcus corresponds approximately to the level of the junction of the urethra with the

bladder although it is produced as the result of the topography of an underlying fascial layer. The upper limit of the bladder in the anterior vaginal wall is defined by a sulcus which is best referred to as the bladder sulcus. A little above the level of the meatus in the anterior vaginal wall on each side is an oblique vaginal fold which passes downward and forward from the lateral side of the vagina. Between the transverse sulcus and the submeatal sulcus the vaginal wall is rugose.

In some cases of prolapse the area of the vagina between the submeatal and transverse sulci is prolapsed and stretched when the two sulci can be easily identified. At other times the two sulci remain approximately in their normal position. In cases of cystocele the main part of the prolapse is almost always between the transverse and bladder sulci. In the surgical treatment of cystocele the object should be to prevent the bladder from prolapsing in the area between the transverse vaginal and the bladder sulci.

ANATOMY OF THE VAGINAL FASCIAL LAYERS

If the cervix is pulled down in a case of prolapse so that the anterior vaginal wall is put on the stretch, and a midline incision made, a plane of cleavage called by Amreich the vesicovaginal space can be exposed. The vaginal layer of endopelvic fascia remains adherent to the vagina while the thin vesical fascia adheres to the bladder. The vaginal fascia varies in thickness whereas the vesical fascia is always thin and never well defined. The vesicovaginal space is relatively bloodless and in operations for cystocele if the correct layer of cleavage is found hemorrhage is reduced to a minimum. In old standing cystoceles the space may be obliterated by fibrous tissue and separation is then only possible with a scalpel.

Between the transverse vaginal sulcus and the submeatal sulcus there is no plane of

From the Obstetrical and Gynaecological Department, St. Bartholomew's Hospital, London.

view of the close intimate relationship other than physical of the tissues. On the other hand the morphologic and staining distinctions of the pale epithelium in the breast would indicate a metabolic and functional distinction and difference which in turn might result in and indicate quite different proliferative potentialities

vesicocervical space is one of the most important steps in operations for prolapse

OPERATIONS FOR CYSTOCELE

In cystocele the bladder prolapses in the area between the transverse vaginal sulcus and the bladder sulcus of the anterior vaginal wall. In some cases the posturethral ligament remains firm and hardly prolapses at all while in other cases the ligament is stretched so that the transverse vaginal and the submental sulci are well defined on the prolapsed part. Theoretically the objects of any cystocele operation are first, to mobilize the bladder and to return it to its normal position and secondly to close the area between the upper border of the posturethral ligament and the cervix in such a way that the bladder will not prolapse again. It is insufficient to close the hiatus with the vaginal wall alone for this may stretch again nor is it satisfactory to close the space with the vaginal endopelvic fascia the weakness of which is one of the fundamental causes of the development of the prolapse. This view is at variance with the present day practice. For many years I em-

ployed and devised different methods of pleating and overlapping the fascial tissues which intervene between the anterior vaginal wall and the bladder to form a supporting shelf. Experience has shown that such methods are unnecessary and the method which I describe in the following gives equally good results. The strongest supporting tissue in the vicinity is the posturethral ligament. For this reason I maintain that the bladder must be mobilized and pushed upward and the space closed by suturing the posturethral ligament directly to the cervix itself. This is the fundamental principle of the operation.

I make a midline incision which ultimately passes from the submental sulcus to the bladder sulcus (Fig. 3). From the cervical end of this incision I make a lateral incision on each side. The inclination of the lateral incision depends upon the severity of the prolapse. First the vesicovaginal space must be opened up. The space is found most easily at the cervical end of the incision. The best way is to apply traction to the lower angles of the vaginal flaps. I do not believe that there is any risk of injury to the bladder if ordinary care is

Fig. 1. Anatomical details of the anterior vaginal wall. 1 The hymen. 2 The submental sulcus. 3 Paraurethral recess. 4 Oblique vaginal fold. 5 Transverse sulcus of the anterior vaginal wall. 6 Arched rugae of the vaginal wall. 7 Bladder sulcus.

cleavage for the vesical and vaginal fascias are fused in this area (Fig. 2). There is however a loose space in the vicinity of the rugosities, between the fused fascias and the skin of the vagina with its thin layer of vaginal fascia. A scalpel is required to separate the vaginal wall from the underlying fascial layers in this region.

The fascial tissues which lie deep to the vaginal wall between the submental and transverse sulci form a specialized condensed layer of fascia which I have called the posturethral ligament. To appreciate the importance of the ligament dissection should be made either on a cadaver or at operation in a case of cystocele of slight degree. The ligament extends from an attachment to the pubic ramus of one side below and behind the urethra and the neck of the bladder to the pubic ramus of the opposite side and forms a dense sheet of tissue which supports the urethra and the neck of the bladder. The upper border is well defined and is responsible for the formation of the transverse vaginal sulcus. The ligament mainly consists of plain muscle tissue and if the muscle tone is lost the ligament stretches which leads to urethrocele and contributes to the development of a cystocele. These views

Fig. 2. Anatomy of the fascial layers in the vicinity of the external urinary meatus (diagrammatic). On the left the vaginal fascia and vesical fascia are separated by the vesicovaginal space. Nearer the urethra the vaginal fascia splits into two parts, a thin layer remains attached to the rugosities vaginal wall and is continued forward to point a. The greater part of the vaginal fascia fuses with the vesical fascia to form the posturethral ligament b. Between a and b the tissue is loose connective tissue, which must be cut through with the sharp end of scalpel.

are different from those held by Kennedy. All gynecologists must have recognized the condensation of fascia around the urethra, and the term paraurethral fascia is sometimes used. In view of its condensed consistence of the lateral attachments and the well defined upper border in my view it should receive separate terminology and I have suggested the term posturethral ligament.

Passing from the vesical fascia to the cervix and in consequence fixing the bladder to the cervix is a thin sheet of endopelvic fascia called the vesicocervical ligament (Amreich). On each side the ligament passes into the bladder septum which is a thicker layer of endopelvic fascia which attaches the bladder to the lateral aspect of the cervix. A plea for uniformity of terminology may conveniently be made at this stage. The various fascial layers are known to operating gynecologists, but gynecologists tend to use different names for the same structures. Such terms as subvaginal fascia, paravaginal fascia, pubovesical ligament, pubocervical ligament, pillars of the bladder are employed. The terminology of Tandler and Amreich which I have employed seems to be the most exact and most scientific.

If the cervix is pulled down and the vesicocervical ligament stretched and then divided a bloodless space is found between the bladder and the cervix. This space is called the vesicocervical space. The bladder cannot be mobilized unless this space is defined and until the bladder septa have been divided with scissors. Indeed in my view the identification of the

Fig. 9

Fig. 10.

Fig. 9. Excision of the redundant vaginal wall together with the vaginal fascia.

Fig. 10. The key sutures. Above, the suture passes first through the vaginal wall together with its vaginal fascia, then through the posturethral ligament, then through the front of the cervix, then through the posturethral ligament and the vaginal wall of the opposite side. The lower sutures pass through the vaginal wall and the vaginal fascia then through the front of the cervix and then through the vaginal fascia and the vaginal wall of the opposite side.

stretched and sometimes it may be necessary to pass the suture through the uterovesical pouch. The suture is then passed through the posturethral ligament on the other side of the midline at a corresponding point and then through the vaginal fascia and vaginal wall as before. When this suture is tied the space through which the bladder can prolapse is obliterated completely (Fig. 11). Reinforcement sutures can be introduced when necessary.

In my view this particular suture is one of the most valuable in the whole of vaginal surgery for prolapse. Sometimes a series of interrupted sutures can be passed between the posturethral ligament and the front of the cervix and many minor modifications of the technique are obviously possible. Clearly one of the great advantages of the technique is that the urethra is stretched longitudinally, which is of the utmost service in the cure of stress incontinence.

No effort is made to dissect the vaginal fascia from the vagina and to interpose a layer of

fascial tissues between the vaginal wall and the cervix for the view is taken that the fascial layers are atonic in cases of prolapse and have little supporting action. The cervix part of the incision is now closed with interrupted sutures. Each suture passes through the vaginal wall and vaginal fascia, then through the front of the cervix and then through the vaginal fascia and vagina of the opposite side. This series of stitches should close still more the pre-existing space through which the bladder has prolapsed. At the other end of the incision it may be thought advisable to introduce a series of interrupted Lembert sutures through the posturethral ligament if there is a tendency to urethrocele or stress incontinence. The cut vaginal wall is then closed by a series of interrupted sutures.

A self retained catheter is introduced into the bladder and retained for at least 5 days. It is found in practice that most patients have great difficulty in voiding urine for nearly a week after the operation. The end results are extremely satisfactory.

taken. If the correct layer is found the vagina, together with its fascia, strips easily and a few delicate touches with the scalpel combined with separation with dry gauze wrapped round the finger will open up the space as far upward as the posturethral ligament (Fig. 4). If the correct layer is found there is little or no hemorrhage for the vaginal vessels lie in the vaginal fascia and the vesical vessels lie in the vesical fascia. When the posturethral ligament is reached it is necessary to use a scalpel to cut through that part of the vaginal fascia which merges with the posturethral ligament and over the surface of the posturethral ligament a scalpel must be used to separate the vagina with its rugose pouches from the ligament (Fig. 5). The next step is the usual division of the vesicocervical ligament and the division must be carried sufficiently deeply to expose the bloodless white space of the vesicocervical space (Fig. 6). The bladder cannot be sufficiently mobilized however until the bladder septa have been divided to a moderate extent on each side. The bladder must be mobilized sufficiently so that it can be pushed upward to expose the uterovesical pouch of peritoneum (Fig. 7). The next step is to excise

the redundant vaginal wall and its underlying fascia from the two lateral flaps and it is at this stage that the vaginal vessels are divided and they must be ligatured separately (Figs. 8 and 9).

The crucial suture is now introduced. It passes through the vaginal wall and vaginal fascia, starting at a point 3 to 4 centimeters below the meatus, about $\frac{1}{2}$ centimeter from the cut edge. The needle is passed through both the vaginal wall and the vaginal fascia (Fig. 10). It is then passed through the posturethral ligament on the same side of the midline. There is plenty of tissue to pick up and there is no risk of injury either to the urethra or to the bladder. Before the suture is passed through the ligament the ligament should be pulled upward in the direction of the cervix and the ligament should be transfixed in the average case about half way between the submental sulcus and the cervical edge of the posturethral ligament. The suture is now passed through the front of the uterus. The level of the uterus at which the suture is introduced depends upon the severity of the case. The higher the level of the uterus at which it is introduced the more the urethra will be

Fig 14.

Fig 14. Manchester Fothergill operation. The cervix has been amputated and the lateral pedicles brought forward in front of the cervix.

Fig 15. Manchester Fothergill operation. The post-urethral ligament is sutured to the front of the cervix as in the operation of anterior colporrhaphy, the lower sutures of anterior colporrhaphy are also introduced, while below the lateral pedicles are sutured together and also to the front of the cervix. The theoretical object is to define Mackenrodt's ligament and to put the ligaments on the stretch by stitching them to the front of the cervix in the midline.

a scalpel the fascial tissues lying on the lateral side of the cervix are cut away from the cervix and mobilized for at least $\frac{1}{2}$ inch above the level at which the Weibel clamp has been placed (Fig 13). The same procedure is carried out on the opposite side. If the scalpel cut is sufficiently close to the cervix the risk of hemorrhage is small. Next, the tissues enclosed in the Weibel clamps are ligatured and the ligatures can then be regarded as being attached to the lower ends of Mackenrodt's ligaments. The next step is to suture these two ends to the front of the cervix in the midline and to pass a few interrupted sutures to stitch the two ends together (Figs 14 and 15). The theoretical object of the technique is to define Mackenrodt's ligaments and to put the ligaments on the stretch by stitching them to the front of the cervix in the midline. Moreover, the technique tends to make the uterus anteverted. Some experience is required to determine the extent to which the fascial tis-

Fig 16. Vaginal hysterectomy for prolapse. Suture No. 1 passes through the vaginal wall and vaginal fascia, then through the posturethral ligament, then through the peritoneum. Afterward it passes through the corresponding structures of the opposite side. In this case the peritoneum replaces the uterus in the anterior colporrhaphy technique. Suture No. 2 passes through the vaginal wall and fascia, then through the stump containing the round ligament, ovarian ligament, and fallopian tube, then through the posturethral ligament, and afterward through the corresponding structures of the opposite side.

ues should be mobilized. Obviously if this method is to be employed the Weibel clamp must not include any part of the vaginal epithelium. The cervix is then covered in the usual way by the Bonney Sturmdorf technique.

VAGINAL HYSTERECTOMY FOR PROLAPSE

The variations possible in this technique are almost countless for much depends upon the severity of the associated cystocele and prolapse of Douglas pouch.

A midline incision in the anterior vaginal wall is first made and the lateral incisions at the level of the bladder sulcus are placed transversely. The two vaginal flaps are dissected away as in the anterior colporrhaphy technique. The vesicocervical ligament is divided, the vesicocervical space is opened up and the bladder mobilized. If the cystocele is extensive the bladder should be invaginated with a pursestring suture or with a series of

Fig. 1

Fig. 2

Fig. 3

Fig. 1. The illustration shows how the tightening of the anterior key suture brings down the postuterothral ligament and fastens it to the front of the uterus and cervix. In this way the ligament is elongated and the space through which the bladder has prolapsed becomes closed.

Fig. 3. Manchester Fothergill operation. After the lateral tissues have been ligatured the stump is mobilized

by means of incisions placed immediately lateral to the cervix.

THE MANCHESTER FOTHERGILL OPERATION

The principles of the method of anterior colporrhaphy are incorporated in the technique I use for the Manchester Fothergill operation. A midline incision in the anterior vaginal wall is first made and the lateral incisions in the vicinity of the bladder sulcus are made at right angles, but are not at first carried round the cervix to encircle the cervix. The lateral vaginal flaps are dissected away as before the vesicocervical ligament divided and the bladder mobilized. The lateral vaginal flaps are excised and the key sutures passed through the vaginal wall vaginal fascia postuterothral ligament and the front of the supravaginal portion of the cervix exactly as in the anterior colporrhaphy technique (Fig. 15).

The next step is to continue the lateral incisions around the cervix and the level at which the incision is made depends upon how much of the cervix is to be removed. Next on each side a strong curved clamp of the Weibel pattern is used to clamp the paracervical fas-

cial tissues which enclose the vessels which run laterally along the cervix (Fig. 12). If prolapse of the uterus is well marked the clamp is placed on the fascial tissues alone but if the prolapse of the cervix is only of a moderate degree it may be expedient to enclose the squamous epithelium layer covering the back of the cervix in the clamp for the cut surface exposed after the cervix has been amputated can be covered with epithelium more easily if this step is taken.

The Manchester Fothergill operation gives exceptionally good results in selected cases, probably because redundant vagina from the vicinity of the posterior fornix is stretched to cover the cut surface of the posterior half of the cervix. If there is well marked prolapse of the uterus Mackenrodt's ligaments are stretched and the slackened ligaments must be tightened at operation. To carry out this procedure satisfactorily the following technique is employed. The cervix is amputated in the usual way and with the help of volsellum forceps the cut surface of the cervix is pulled to one side. With

making a longitudinal incision in the posterior vaginal wall from the opening in Douglas pouch otherwise the ligaments cannot be exposed sufficiently accurately (Fig. 17). The tissues contained in the other clamps are sutured together by the usual Mayo-Ward method, and it is often expedient to delay this suturing until this stage of the operation has been reached.

OPERATIONS FOR STRESS INCONTINENCE

Vaginal operations for the relief of stress incontinence have one factor in common—the originators always claim good results. It is doubtful whether the Stoeckel Goebell technique, or the more modern Aldridge method of sling operation, should be employed unless efforts at vaginal repair have failed. I am quite satisfied that if the urethra is elongated in the methods I have described for anterior colporrhaphy the Manchester Fothergill operation and vaginal hysterectomy the stress incontinence is usually relieved provided that the elongation is of a sufficient degree. Further more it is quite simple to interpose an additional supporting shelf beneath the urethra by a series of Lembert's sutures through the post

urethral ligament. Indeed I have obtained better results by such methods than by the Kelly technique. The etiology of stress incontinence is obscure and I am convinced that there are many underlying etiological factors. Some of the worst cases result from anterior colporrhaphy when I believe the nerve supply to the voluntary urethral sphincter is divided. In the average case of stress incontinence the external meatus is patulous and prolapsed downward and forward and together with the lower $\frac{1}{2}$ inch of the urethra projects well below the inferior pubic angle.

I think most gynecologists will agree that in a certain proportion of cases stress incontinence recurs after relatively simple vaginal operations. Moreover, the worst cases to deal with are those in which the symptom is present without accompanying cystocele or prolapse of the uterus. Often, the only physical signs are a patulous external meatus combined with prolapse of the urethra and the lower third of the anterior vaginal wall. I have never been particularly impressed with the Stoeckel Goebell or the Aldridge operation, mainly because the fascial strips which act as a sling are too narrow. I have therefore, attempted to

Fig. 7. Vaginal hysterectomy for prolapse. Suture No. 1 brings together the mid pedicle. Suture No. 2 brings together the pedicle of the uterosacral ligaments. If there has been an enterocele, suture No. 3 passes through the uterosacral ligament pedicle, then through the mid pedicle and passes in front to be sutured to the postuterothral ligament. Sutures 1 and 2 of Figure 15 and suture 3 of Figure 6 are not tied until all three sutures have been introduced.

Fig. 8. The fascial strip taken from the fascia lata showing the approximate measurements.

reefing sutures. The uterovesical pouch is now opened up and the layer of peritoneum near the bladder grasped with long Kocher's forceps. The anterior wall of the uterus is pulled through this opening in the peritoneum and the fundus of the uterus drawn downward. A series of Weibel's clamps is next placed along each side of the uterus and the uterus separated with a scalpel as far down as the uterosacral ligaments. The cervix is drawn upward and the circumcision of the cervix completed by joining the lateral ends of the original incision behind the cervix. The situation of this posterior incision through the vaginal wall depends upon the extent of the enterocele. The next step is to draw the fundus of the uterus downward and to put on the stretch the herniated peritoneum of Douglas's pouch. In this way the peritoneum can be mobilized and the hernial sac, if present, can be excised with scissors. After this, the uterosacral ligaments are clamped and the uterus removed by cutting with a scalpel on the uterine side of the clamps. I now place ligatures around the tissues enclosed in the clamps but do not remove the clamps themselves at this stage. A series of key sutures is then introduced (Fig. 16). The first passes through the vaginal wall and vaginal fascia about $1\frac{1}{2}$ inches below the level of the urinary meatus. It then passes through the postuterothral ligament half way between the meatus and the cervical edge of the postuterothral ligament. Next it passes

through the peritoneum which was grasped in the Kocher's forceps after which it passes through the postuterothral ligament of the opposite side and then through the vaginal fascia and vaginal wall of this side. The suture is not tied at this stage. A second key suture is now introduced. It passes through the vaginal wall and vaginal fascia at a point a little below the introduction of the previous stitch. It then passes through the tissues enclosed in the first clamp which consist of the fallopian tube round ligament and ovarian ligament. It passes through the postuterothral ligament of the opposite side then through the tissues enclosed in the corresponding Weibel's clamp of the opposite side and out through the vaginal fascia and vaginal wall. The first suture is now tied and this brings together the vaginal fascial and the postuterothral ligament, and draws down the peritoneum to stitch it to the postuterothral ligament. In this way an excellent support is obtained which tends to prevent the bladder from herniating again. As a result of the second suture a shelf is formed by the tissues of the upper part of the broad ligament which also prevents the bladder from herniating again.

Next if there has been a well marked enterocele the uterosacral ligaments are sutured directly to the postuterothral ligament and subsequently with a series of interrupted sutures it is possible to suture the two uterosacral ligaments together but this necessitates

Fig. 21. The sling has been sutured in position. Above, one edge of the broad part of the sling has been sutured to the skin remaining around the urethral meatus. It is not advisable to introduce stitches into the wall of the urethra in this region. The other edge of the sling is sutured directly to the cranial margin of the post-urethral ligament. On each side the thin ends of the sling pierce the tissues lying lateral to the urethra.

making a longitudinal incision in the posterior vaginal wall from the opening in Douglas pouch otherwise the ligaments cannot be exposed sufficiently accurately (Fig. 17) The tissues contained in the other clamps are sutured together by the usual Mayo-Ward method and it is often expedient to delay this suturing until this stage of the operation has been reached.

OPERATIONS FOR STRESS INCONTINENCE

Vaginal operations for the relief of stress incontinence have one factor in common—the originators always claim good results. It is doubtful whether the Stoeckel Goebell technique or the more modern Aldridge method of sling operation should be employed unless efforts at vaginal repair have failed. I am quite satisfied that if the urethra is elongated in the methods I have described for anterior colporrhaphy, the Manchester Fothergill operation and vaginal hysterectomy the stress incontinence is usually relieved provided that the elongation is of a sufficient degree. Further more it is quite simple to interpose an additional supporting shelf beneath the urethra by a series of Lembert's sutures through the post

urethral ligament. Indeed, I have obtained better results by such methods than by the Kelly technique. The etiology of stress incontinence is obscure and I am convinced that there are many underlying etiological factors. Some of the worst cases result from anterior colporrhaphy when I believe the nerve supply to the voluntary urethral sphincter is divided. In the average case of stress incontinence the external meatus is patulous and prolapsed downward and forward and together with the lower $\frac{1}{2}$ inch of the urethra projects well below the inferior pubic angle.

I think most gynecologists will agree that in a certain proportion of cases stress incontinence recurs after relatively simple vaginal operations. Moreover, the worst cases to deal with are those in which the symptom is present without accompanying cystocele or prolapse of the uterus. Often the only physical signs are a patulous external meatus combined with prolapse of the urethra and the lower third of the anterior vaginal wall. I have never been particularly impressed with the Stoeckel Goebell or the Aldridge operation mainly because the fascial strips which act as a sling are too narrow. I have therefore, attempted to

Fig. The ends of the sling sutured together in front of the symphysis pubis (diagrammatic). The lower end of the sling can be seen supporting the urethra.

correct the condition by interposing a strip of fascia lata between the anterior vaginal wall and the urethra and supporting the two ends of the strip by boring two holes in the pubic bones and suturing together the ends of the fascial strip in front of the symphysis pubis. The fascia lata strip is fashioned so that it has a broad middle piece which can be sutured in place in such a way that it lies along the whole length of the urethra. Moreover in some cases it may be convenient to suture the upper end of the strip to the front of the uterus itself. The operation details are as follows:

The strip must be 6 inches long and at least $1\frac{1}{2}$ inches wide in its middle part tapering to ends which need not be more than $\frac{1}{2}$ inch in width (Fig. 18). An open operation is required and the severed edges of the fascia lata are sutured together with continuous catgut sutures combined with a few supporting mattress sutures. The fascial strip can be obtained and the wound closed in not more than 15 minutes.

The next step is to incise the vaginal wall in the midline by an incision which starts a few millimeters above the level of the external meatus and extends upward (Fig. 19). At the lower end an incision is made around the urethra on each side in such a way that two lateral flaps can be dissected clear (Fig. 20). If there is an associated cystocele the incision must be carried upward to above the level of the bladder sulcus and the operation for anterior colporrhaphy performed in the usual way. If only a urethrocele is present it may not be possible to carry the incision so far upward. At this stage of the operation the object is to expose the urethra along the whole

of its length and the vaginal flaps must be dissected away laterally the dissection being carried well out to the region of the pubic rami. The fascial strip is now taken and one edge of its midportion is sutured directly to the vaginal skin of a few millimeters thickness which remains around the meatus (Fig. 21). The opposite edge of the broad part of the fascial strip is sutured to the front of the cervix if the patient has been treated by the anterior colporrhaphy technique which I have already described. If however the bladder does not prolapse the upper end of the broad part of the strip is sutured by a series of horizontal interrupted sutures to the upper limit of the posturethral ligament. In this way a broad sheet of fascia lata is placed in position to support the urethra.

The next step is to make a vertical incision on each side of the lower third of the urethra through the posturethral ligament and the underlying tissues until the retropubic space has been opened up.

The next part of the operation has as its object to bore a hole through each pubic bone about $\frac{3}{4}$ inch from the midline of the symphysis pubis. Various methods have been employed to obtain a good exposure. It is possible to make an incision on each side along the groove immediately lateral to the labium majus $\frac{1}{2}$ inch below the adductor longus tendon. This area is relatively bloodless. The labium majus is drawn inward and the pubic bone exposed by dissection and with the use of a rugine. The disadvantage of this method is that when the end of the fascia lata strip is drawn through the hole in the bone it must be sutured to the periosteum for it cannot be sutured to the opposite end so that the amount of tension on the sling is uncertain. Another method which I have employed has been to make an arched incision over the lower part of the symphysis pubis and the bodies of the pubic bones after first drawing the labia minora upward. The method gives a simple approach to the bones but it has certain grave disadvantages. In the first place, the urethra and the meatus tend to fall upward into the vagina when the patient is in the lithotomy position. Next the holes made in the bones are too low down so that the fascial sling is

Fig. 23. Diagrammatic representation of the method of slinging up the urethra to the symphysis pubis. This illustration should be compared with the direction of the sling in the Aldridge operation. With the method illustrated there is no risk of kinking the urethra.

not supported in the correct direction. Another method is to make an arched incision with its upper limit at the level of the base of the clitoris which corresponds to about half way down the symphysis pubis, with the lateral vertical limbs of the arch, each at about $1\frac{1}{2}$ inches from the midline. It is a simple procedure to find the correct layer between the tendinous structures attached to the bones and the superficial tissues of the mons. Venous hemorrhage is troublesome just as in a Pfannenstiel incision, and great care must be taken to ligature every vessel because of the risk of the development of a hematoma. Experience has shown that the most satisfactory of the three methods of approach is by means of the incisions lateral to the labia majora. Excellent results have been obtained and it does not seem to be of importance to gauge the amount of tension placed on the sling with very great accuracy. It seems necessary only to suture the ends of the sling to the periosteum and the tendinous structures attached to the bones. The bodies of the pubic bones are cleaned with a rugine and the bones are perforated about $\frac{1}{2}$ to $\frac{3}{4}$ inch from the midline with a simple brace and drill. An assistant can introduce a finger through the vagina into the retropubic space to prevent damage to the bladder. There seem to be no technical difficulties in drilling the bone and there seems to be little risk of damage to the bladder. One of the most difficult parts of the operation is to bring the ends of the fascial strip through the drill holes. A piece of catgut is tied to the end of the fascial strip and a long curved needle 3 inches in

Fig. 24. The fascial sling is shown in position supporting the urethra, while to the left is the aperture through the pubic bone through which the end of the sling has been passed.

diameter is passed eye end first from in front through the drill hole then behind the pubic bone through the incision in the post-urethral ligament and the catgut attached to the strip threaded through the eye of this needle. The needle must be of the correct size and have a full half circle curvature. The end of the strip can then be brought out through the front of the drill hole in front of the pubic bone. The two ends are then sutured together and the correct amount of tension obtained (Fig. 22). It is an extraordinary sight to see how the urethra can be pulled up to lie in the correct position. This part of the operation compares most favorably with the other methods of sling operation. With the other methods of approach a few sutures are introduced to attach the strip to the periosteum near the trephine hole. Penicillin powder is now introduced into the wound particularly near the trephine holes. The great objection to drilling the pubic bones is the theoretical risk of osteomyelitis although this complication did not develop in any of my cases. I felt therefore that the operation would be simplified if the end of the fascial strip were brought out through the lower angle of the obturator foramen. Much time was spent working with models and although I realize that the sling support is not so effective in direction when the ends are brought out through the obturator foramina. I tried out the method in a few cases and obtained excellent results. At the present time I have abandoned the method of drilling the pubic bones except for what I regard as severe cases. In the method of bringing the ends of the sling through the obturator foramen vertical incisions are made on the

outer sides of the labia majora and the tissues are cut through down to the obturator foramen with a scalpel. A specially curved forceps with toothed ends is then passed through the obturator foramen in front and brought down lateral to the urethra as in the other methods and the end of the strip is sutured to the deep tendinous tissues in the vicinity of the obturator foramen. The operation is extremely simple to perform and the results obtained are satisfactory.

Up to the time of writing 25 patients have been operated upon and the end results have been extremely satisfactory. My own impression is that the results are already far better than those I have obtained with the Aldridge operation and the broad support of the sling is obviously theoretically correct.

The characteristic optimism of all originators of operations for stress incontinence has been discounted so far as possible. Fundamentally the idea behind the operation is to replace the posturethral ligament by the strip of fascia lata. Only time will show whether the fascia will produce a permanent support. The method has other possibilities for a wide sling might be used in the treatment of severe degrees of cystocele.

SUMMARY

1. The anatomical details of the grooves, rugosities and folds of the anterior vaginal wall have been described.

2. The anatomical relations of the endopelvic fascia in the vicinity of the anterior vaginal wall have been discussed.

3. A condensation of the endopelvic fascia behind the urethra has been described and the term posturethral ligament has been used to describe this band.

4. An attempt has been made to describe the operation of cystocele on a purely anatomical basis, and a method of suturing the posturethral ligament to the cervix has been described.

5. Details have been given of the method of using the posturethral ligament in the operation of vaginal hysterectomy for prolapse and in the Manchester Fothergill operation.

6. A new method of sling operation for stress incontinence has been described. It consists of utilizing a sheet of fascia lata as a sling behind the urethra and bringing the two ends together through holes bored through the pubic bones.

EXPERIMENTAL PULMONARY EMBOLISM

WILLIAM D HOLDEN M.D., F.A.C.S. Cleveland Ohio BYERS W SHAW M.D., Cleveland Ohio DONALD B CAMERON M.D. Cleveland Ohio PATRICK J SHEA, Jr. M.D., Emory University Georgia and JOHN H DAVIS Jr., M.D. Cleveland, Ohio

THIS experimental study was conceived with the object of determining whether or not pulmonopulmonary, pulmonovagal depressor and pulmonocoronary reflexes contributed to the death of animals subjected to massive pulmonary embolism. The literature is extensive on this subject and has been reviewed by Horn Dack and Friedberg in 1939 and Currrens and Barnes in 1943. Reference will be made only to articles pertinent to the present study.

One of the principal objections to experimental studies on pulmonary embolism is that the embolus does not simulate that found in the human being. For anatomic and histologic observations of the pulmonary parenchyma, any foreign body that occludes pulmonary arteries may be used. Progressive thrombosis of the pulmonary arteries and retrograde thrombosis into the right ventricle following lodgment of emboli in the pulmonary arteries are not well understood and may be of considerable clinical importance. Thrombosis superimposed on an embolus cannot be satisfactorily studied in the experimental animal that has an artificial foreign body occluding a pulmonary artery. This objection has been minimized in the present study.

Another objection that has been raised is that the depth of anesthesia in experimental work of this nature precludes accurate observation of reflex changes. Care was taken to avoid deep anesthesia and in practically all the animals gentle manipulation of blood vessels in the periphery produced slight pseudo-affective responses.

Forty adult, healthy mongrel dogs weighing 7 to 15 kilograms were lightly anesthetized with sodium pentobarbital administered

intravenously. An endotracheal tube was inserted in those animals which were to have the thoracic cavity opened. A mechanical positive pressure respirator was attached to the tube. Both external iliac veins were exposed retroperitoneally up to the internal iliac veins. The common femoral veins were exposed and all branches ligated with No. 000 silk. Soft rubber bulldog clamps were applied to the external iliac veins just distal to the internal iliac veins. Five hundred units (0.5 c.c.) of thrombin were injected into each iliofemoral vein through a No. 27 needle. Five puncture sites were used on each side. Each vein was gently massaged two or three times to insure adequate mixing of the thrombin and blood. Within a few minutes a firm thrombus could be palpated through the wall of the vein. In the open chest preparation the left costal cartilages were cut and the thoracic cage spread apart until adequate exposure of the base of the heart was obtained. A metallic cannula was inserted into the left common carotid artery and connected to a calibrated mercury manometer which recorded partially dampened pressures on a kymograph. A brass cannula 15 centimeters in length was inserted into the right atrium through the left external jugular vein. A column of 0.25 per cent sodium citrate was connected to the cannula and to a recording device to determine venous pressure directly. An electrocardiograph recorded the conventional three leads in 11 animals. After basal records of the arterial and right atrial pressures were taken the clamps were simultaneously or consecutively removed from the iliac veins.

Twenty five animals were used in studying the dynamics of pulmonary embolism without nerve section or intravenous papaverine. Three were used to establish a satisfactory method of recording pressures. One died during insertion of the atrial cannula. Nine died

within 5 minutes after release of the emboli. Twelve were sacrificed after apparently having recovered from the embolism. Of these 12 dogs 8 had emboli obstructing the main pulmonary arteries. Four had embolic obstruction of only one pulmonary artery. After release of the emboli the following characteristic sequence of events occurred. Within 2 to 5 seconds, the dog developed marked respiratory distress, a precipitous drop in arterial pressure, tachycardia, and an elevation in atrial pressure. In the dogs that succumbed the respiratory rate increased, became irregular and then slowed progressively during the ensuing few minutes. The depth of the respiratory excursion increased until only infrequent gasps were observed. During the same period the arterial pressure dropped progressively, the cardiac rate became slower and venous pressure rose several centimeters of water. In none of the 40 dogs was ventricular fibrillation or abrupt cessation of cardiac activity observed. Cardiac contractions became progressively slower and more feeble until all muscular activity ceased. Respirations invariably stopped in the closed chest preparations before cardiac contractions ceased. The initial stimulation of respiratory rate and depth can best be explained by the superior vena caval reflex described by Megibow, Katz and Feinstein. The cessation of respiration, however, before cardiac activity ceased accompanied in all instances a progressive systemic hypotension and was probably a dependent upon cerebral ischemia. In the open chest preparations, dilatation of the pulmonary conus, right ventricle and atrium (Fig. 1) was striking in the dogs that did not survive. Distension of the coronary veins was noted.

The heart and lungs were examined immediately after death or sacrifice and sections taken whenever it was thought advisable. The right heart of all animals was dilated. The dilation however was less striking than in the living animal. The emboli were easily recognized and found consistently in the major pulmonary arteries (Fig. 1). On occasion embolic fragments were found caught in the chordae tendinae in the right ventricle and on 2 occasions embolic obstruction occurred at the tricuspid valve. The emboli were firm homo-

geneous and purplish-red. On many occasions recently formed thrombi were observed extending into branches of the pulmonary arteries. They were also found in the right ventricle. They differed from the emboli in that they were soft and bright red. The last 13 animals were heparinized with 10 milligrams of heparin given intravenously after the thrombi were formed in the iliac veins. It was our impression that the heparinized animals underwent less severe changes in pressure after embolism. Individual variation, however, was sufficiently great so that no exact statement can be made on this aspect of the experiment. Examination of the pulmonary arteries of the heparinized animals revealed the emboli to be farther out in the divisions of the main pulmonary artery than was seen in the nonheparinized animals. The formation of thrombi in the branches of the pulmonary arteries was conspicuously absent in these animals. The left atrium and ventricle, aorta and inferior vena cava were routinely opened and on no occasion was the blood coagulated. Contrary to the findings of Megibow, Katz and Feinstein the lungs of the dogs that died within 2 to 10 minutes showed areas of atelectasis, and diffuse or focal ecchymosis. Figure 2 shows the two lungs of a dog that died 5 minutes after release of the emboli. Sections of the right and left lung are shown in Figures 3 and 4. Atelectasis, diapedesis of erythrocytes, and interalveolar hemorrhage are noted in Figure 4 whereas little change is observed in the lung that had only partial embolic obstruction of its artery (Fig. 3).

In the animals that survived the initial emboli characteristic changes occurred in their cardiovascular dynamics. Arterial pressure dropped immediately 20 to 40 millimeters of mercury and returned to the initial level or above within 5 seconds to 1 minute. Right atrial pressure rose 20 to 40 millimeters of water and gradually over a period of 2 to 3 minutes returned to normal (Fig. 5). Respiratory changes were variable in this group. In general the rate increased for a few seconds. The depth of respiration however increased or decreased and on occasion no change was noted.

In all but 1 of the experiments in which the animals survived the initial emboli the pres-

Fig. 1. The pulmonary conus, right and left pulmonary arteries have been opened. Emboli lying in both pulmonary arteries can be seen. The right side of the heart is dilated and the distended coronary veins are seen.

sure in the right atrium promptly returned to normal levels. In view of this observation it is unlikely that reflex vasoconstriction of the pulmonary arterial tree occurs in sublethal embolism. The readjustment of blood volume in the pulmonary circuit and the response of the right ventricle to the increased pulmonary resistance explain more simply the rise and fall of right atrial pressure.

Fig. 3. The microscopic appearance of the relatively normal lung in Figure 2.

Fig. 2. Cross appearance of the right and left lung 5 minutes after a fatal embolus. The pulmonary artery to the lung on the left was partly obstructed. The glistening surface may be seen. Complete obstruction was present on the right and the echymosis and loss of luster are noted.

One of the most impressive observations made on these 40 animals was the marked degree of obstruction in the pulmonary arteries necessary to produce death. In many of the dogs that were sacrificed a large part of the pulmonary circuit was obstructed and yet dynamic changes during the embolism had been slight and temporary. In these animals however there was reason to believe that with

Fig. 4. The microscopic appearance of the lung whose pulmonary artery was completely obstructed (Fig. 2). Atelectasis and interalveolar hemorrhage are noted. A branch of the pulmonary artery containing an embolus can also be seen.

Fig. 5 The top record indicates left carotid blood pressure, the center I time in seconds and the lower right atrial pressure. E designates the release of the thrombus from the iliac vein. The fall in carotid pressure and the rise in atrial pressure were found in all animals.

superimposed thrombosis, death would have ultimately intervened.

Electrocardiographic tracings in 11 experiments showed no consistent alteration in pattern. Depression of the S-T segment in lead III was encountered in 6 dogs. Inverted and diphasic T waves were seen in lead III on 5 occasions. Prominent Q waves were observed 3 times in leads I and III. A shifting pacemaker was observed once and arteriovenous dissociation once. In fatal instances gradual slowing of the auricular rate was seen. No ventricular fibrillation was recorded.

For many years a controversy has existed concerning the presence or absence of pulmonovagal reflexes in pulmonary embolism. Schwiegk, Schweitzer and Parin observed that distention of the pulmonary arteries produced a reduction of systemic arterial pressure that was abolished by section of the cervical vagi. Parin suggested that the systemic hypotension not uncommonly observed in pulmonary embolism may be due to such reflex activity. A pulmonovagal-coronary reflex reducing coronary blood flow has never been demonstrated experimentally but has been invoked on many occasions to explain death in pulmonary embolism. The suggestion that a pulmonocoronary reflex exists in pulmonary embolism is based in part on clinical evidence. Leriche, Fontaine and Friedmann reported 30 per cent of their patients who died after pulmonary embolism had only partial occlusion of the pulmonary arteries. De Takats, Beck and Fenn noted that a typical death from pulmonary embolism occurred in the pres-

ence of minor pulmonary obstruction in 7 out of 35 cases. On the other hand, Pilcher in a postmortem study of 40 patients who died following pulmonary embolism observed mechanical obstruction sufficient to cause death in 37. Karsner has never observed death as a result of a minor embolism without some contributing cause being present such as cardiac failure or coronary arteriosclerosis. Horn, Dack and Friedberg observed that morphologic evidence of coronary insufficiency in cases of embolism of the pulmonary artery is more likely to occur if there are recurrent embolization, narrowing of the coronary arteries, cardiac hypertrophy and adequate duration of life after embolism.

The experimental evidence in favor of a pulmonocoronary reflex has resulted from survival studies after cervical vagotomy and atropinization. Electrocardiographic studies before and after vagotomy and atropinization in pulmonary embolism have also contributed to the acceptance of such a reflex. Mosler, Radnai and Mosonyi and Scherf and Schonbrunner after studying electrocardiographic changes in pulmonary embolism and the results of vagal section and atropinization concluded that vagal stimulation had decreased coronary blood flow. Love, Brugler and Winslow felt that similar electrocardiographic changes could be ascribed to mechanical obstruction of the pulmonary circuit. Malinow, Katz and Kondo stated that bilateral cervical vagotomy did not abolish the electrocardiographic alteration produced by emboli in dogs and that there was no evidence for assuming the existence of a pulmonocoronary constricting reflex in pulmonary embolism. De Takats, Beck and Fenn observed a 33 per cent mortality with atropine and 60 per cent with vagotomy in dogs which were subjected to embolism. A control series had a 100 per cent mortality rate.

Experimental work has demonstrated that mechanical obstruction of the pulmonary circuit is necessary to produce death. Mann introduced paraffin and blood clots formed *in vitro* into the venous circulation and found that death occurred only in the presence of considerable obstruction to pulmonary blood flow. Hall and Ettinger concluded that re-

Fig 6 The upper pressure recording is the carotid blood pressure and the lower the right atrial. Cervical vagotomies were performed as indicated on the graph. The emboli were released at E_1 . The same changes in pressures were observed. Tachypnea did not develop.

Fig 7 This is a continuation of the record in Figure 6. At E_2 emboli were released. Seventy five per cent of the pulmonary arterial circuit was occluded at autopsy.

flexes did not contribute to death in experimental embolism. Mendlowitz using a Penrose tube filled with dilute barium sulfate studied cardiac dynamics after a major embolism in dogs and concluded that the type of circulatory failure resulting was due only to mechanical obstruction of blood flow in the pulmonary circuit.

Eight dogs were subjected to cervical vagotomies and 4 dogs had resections of the stellate and upper four thoracic ganglia as well as vagotomies. Changes in hemodynamics were consistent and precisely what were encountered in the control experiments. Arterial pressures were reduced as rapidly and extensively as before. In the dogs that survived the initial emboli, arterial pressures returned to normal within 1 to 2 minutes. Changes and readjustments in right atrial pressure similar to those in the control animals were observed in this group. No more emboli were required to produce death than in the control series.

Protocol 32. A 15 kilogram dog was anesthetized with intravenous nembutal and an endotracheal tube inserted to insure a free respiratory passageway. The thoracic cavity was closed throughout the experi-

ment. Left carotid and right atrial pressures were recorded as previously described. The pulse and respiratory rate were recorded. A three lead electrocardiogram was taken before and during the experiment. The external iliac veins were exposed retroperitoneally up to the common iliac veins. All branches of the external iliac and common femoral veins were ligated. Five hundred units of thrombin were injected into each common femoral and external iliac vein at 5 sites through a No. 27 gauge needle. The cervical vagi were exposed and sectioned. Figure 6 shows the result of the vagotomy and the pressure changes observed after release of the first emboli. Arterial pressure dropped 40 millimeters of mercury. A slight temporary reduction in pulse pressure was observed. Venous pressure rose 25 millimeters of water and the depth of respiratory excursions increased. The dog recovered within 2 minutes. Ten minutes later a second embolus was released. The same change in dynamics occurred except several minutes transpired before recovery was complete (Fig 7). A third embolus was released with similar alterations in pressures observed following which the animal was sacrificed by injecting 10 cubic centimeters of nembutal intravenously. The thoracic viscera were examined. Multiple areas of ecchymosis and atelectasis were observed in all lobes of the lungs. The right heart was dilated and coronary veins distended. On opening the heart, the left ventricle and atrium contained a small amount of bright red blood. The right pulmonary artery was obstructed by a large embolus. The left pulmonary

Fig. 8. Both vagi and upper thoracic sympathetic chains are removed. The emboli are released. F. The upper record shows the profound drop in carotid pressure. The lower record is right atrial pressure.

artery contained an embolus which occluded no more than 50 per cent of its lumen. An embolus was lodged between chordae tendinae in the right ventricle.

Protocol 30. This animal was prepared as all others. In addition however the cervical vagi, stellate ganglia and thoracic sympathetic chains (T₂ to T₅) were removed. The thoracic cavity was then closed while positive pressure was applied to the respiratory tract through an endotracheal tube. Figure 8 shows the immediate reduction in arterial pressure and rise in venous pressure with death ensuing 2 minutes after release of the embolus. Obstruction of both pulmonary arteries was found at autopsy.

Dog 38 was subjected to both bilateral vagotomies and cervicothoracic sympathectomies. After release of the emboli, arterial pressure fell and venous pressure rose transiently in the same manner as observed in the control animal.

Papaverine has been enthusiastically advocated in the treatment of pulmonary embolism. The use of this drug is based on the well known clinical and experimental observation that embolic obstruction of a peripheral artery induces in many instances an intense spasm of the arterial tree of the extremity both distal and occasionally proximal to the site of obstruction. It is also well established that papaverine relaxes smooth muscle (Pal) and produces vasodilatation (Macht 16 and Macht Herman and Levy 17). From these facts it has been postulated that a pulmonopulmonary vasoconstricting reflex occurs in pulmonary embolism and that it may be advantageously abolished by the administration of papaverine. Collins de Takats, Denk, Burk, Domanig, Katz and Barnes have advised the use of papaverine to relax the pulmonary arterial system. Jesser and de Takats in an experimental study showed that the vascularity of the pul-

monary arterial tree increased after the intravenous administration of papaverine immediately following embolism of a major artery. No conclusions could be drawn however as to the presence of arteriospasm before the use of papaverine or arteriodilatation afterward. In a series of 10 dogs subjected to massive embolism and given papaverine they obtained a mortality rate of 40 per cent whereas a control group of 25 all succumbed. Bradshaw and Chodoff studied the effect of papaverine on the pulmonary circulation of 20 cats. Transient depression of the systemic pressure and transient elevation of the pulmonary pressure were consistently found. After embolization with oil similar but greater changes occurred.

Three dogs were given papaverine intravenously before and after embolization in doses ranging from 0.0032 to 0.016 gram. Similar changes were observed in the 3 experiments. Dog 34 was given 0.0032 gram of papaverine intravenously. The systemic arterial pressure fell abruptly but returned to normal levels within 20 seconds. The decrease in atrial pressure was observed on several other occasions and is not in accord with Bradshaw and Chodoff's observations. The most striking feature of all papaverine injection however was the transient nature of the effects on the cardiovascular system. Figure 9 shows the result of administering 0.0032 gram of papaverine im-

Fig. 9. An embolus is released. F. The reduction in carotid pressure (upper) and elevation of right atrial pressure (lower) are seen. 0.0032 gram of papaverine is administered intravenously and secondary drop of carotid pressure is noted. The temporary interruption of the rising right atrial pressure is seen also.

mediately after release of emboli. A temporary reduction of atrial pressure occurred but it was immediately followed by a persistent elevation. This same dog was subsequently given 0.016 gram of papaverine intravenously with the characteristic depression of both carotid and right atrial pressures (Fig. 10). At autopsy it was estimated that 90 per cent of the pulmonary arterial circuit was obstructed with emboli in the main pulmonary arteries. Atelectasis and ecchymotic areas were observed in all lobes except the right lower.

Dog 35 was given 0.0064 gram of papaverine intravenously and displayed a reduction in systemic pressure of 40 millimeters of mercury but no change in atrial pressure. Thirty seconds later emboli were released and the customary changes in pressures were observed. After stabilization of the pressures had occurred the experiment was repeated with the same results. Papaverine given 2 minutes after recovery produced depressions of carotid pressure and right atrial pressure which returned to normal in 30 seconds. After pressures had become stabilized embolization was repeated followed by papaverine in 2 minutes. Again reductions in arterial and atrial pressures were observed. At autopsy a saddle embolus was found with moderate patchy atelectasis and intrapulmonary hemorrhage.

DISCUSSION

It cannot be denied that deleterious reflexes may contribute to death in pulmonary embolism in the human being. It would indeed be strange if autonomic reflex activity did not increase when a large portion of the pulmonary circuit is suddenly obstructed.

Our experimental findings do not support such a view but are more in accord with the conclusions of Hall and Ettinger and Mendlowitz. In the 40 dogs studied in this series no hemodynamic changes were observed that could not best be explained on a mechanical basis. Depending upon the amount of pulmonary obstruction systemic arterial pressure fell moderately or slightly and recovered promptly as blood flow through the unobstructed portion of the pulmonary circuit increased. As obstruction became more complete systemic pressure fell progressively un-

Fig. 10. This record is a continuation of Figure 9. 0.016 gram of papaverine administered intravenously temporarily depressed both carotid and right atrial pressures.

til death occurred. Pressure in the right atrium rose in a fashion corresponding to the depression in arterial pressure. No dogs died suddenly suggesting coronary artery spasm. All the dogs who were subjected to vagal section and removal of the stellate and upper thoracic sympathetic ganglia exhibited the same dynamic changes as the control group.

Our experience is in accord with Katz's suggestion that electrocardiographic patterns suggesting coronary insufficiency are the result of a combination of reduced aortic pressure and increased pressure in the right heart interfering with venous drainage from the myocardium.

So far as a pulmonopulmonary reflex is concerned there is no evidence in this study that such exists. In all instances of embolism whether the vagi and sympathetic chains are intact or not the changes in systemic and right heart pressures are transient if the dogs survive and are readily explained on a basis of mechanical readjustment of pulmonary circulation. In the animals that succumb systemic pressure becomes progressively lower and right atrial pressure higher. These animals all have at least 70 per cent of the pulmonary circuit mechanically obstructed. On no occasion was a persistent elevation of right atrial pressure observed which could be explained on a basis of pulmonary arterial spasm.

The reduction of right atrial pressure after the administration of papaverine could be in

THE NATURE OF LATERAL "ABERRANT" THYROID TUMORS

SHIELDS WARREN M.D. and J. D. FELDMAN M.D. Boston, Massachusetts

A CONTROVERSY has existed for many years concerning tumors of thyroid tissue in the lateral regions of the neck. In the earliest reports of these tumors the opinion was held that they represented neoplasia of aberrant thyroid tissue. But the association of lateral cervical tumors with neoplasm of similar structure within the thyroid gland in many if not in all the cases has recently led to the opinion that they represent secondary rather than primary growths. From the evidence adduced at the present time it is clear that lateral thyroid tumors must be appraised in relation to tumors of the main thyroid gland. There are three possibilities to consider: (1) lateral thyroid tumors originate in thyroid tissue which is separated from the thyroid gland by defective embryogenesis and in the majority of cases metastasize to the thyroid; (2) tumors in thyroid and aberrant thyroid tissue represent multicentric neoplastic growth in a single type of embryonal rest; (3) they are early metastases from a tumor of the thyroid gland and become clinically apparent before the tumor of the thyroid manifests itself.

It is the purpose of this paper to determine what features connected with the growth of these tumors can be considered as evidence for one or another mode of origin. For this purpose we shall present an analysis of all the lateral thyroid tumors received in the laboratory of the New England Deaconess Hospital¹ over a period of 19 years.

MATERIAL

There were 63 cases diagnosed as lateral aberrant thyroid tumor among approximately 20,000 surgically removed thyroids in a 19 year period; an incidence of slightly more than

0.3 per cent. This series also represents 3.9 per cent of 1,610 benign and malignant thyroid tumors in the surgical material. Selection of cases was determined by the clinical or pathological diagnosis. The clinical diagnosis was made on the observation that a lateral mass or masses was palpable while the thyroid gland was and remained clinically negative; that the lateral mass was larger than any nodule felt in the thyroid gland; or lastly, that a cervical mass was present before the thyroid was noticeably affected. Occasionally the diagnosis was based on the microscopic findings by the pathology department.

In 57 cases the clinical diagnosis of lateral thyroid tumor was confirmed by the histological examination. There were 6 remaining cases which were not confirmed by microscopy. Of these latter 2 were metastatic tumors unrelated to thyroid tissue; they were single nodules of cancer present in the lateral side of the neck. In 4 cases colloid adenomatous thyroid tissue unconnected with the thyroid gland was present. Two of these patients had been operated upon elsewhere 3½ and 30 years previously, following which adenomatous tissue developed in an aberrant site. A third had cancer of the lung for which a biopsy of a single cervical nodule was performed and this proved to be colloid adenomatous thyroid tissue. His thyroid was not investigated. The fourth was a woman with goiter of 17 years duration who had a small mass in the left supraclavicular area near to but unconnected with an enlarged non-neoplastic adenomatous left lobe.

The observations to be made in the following are concerned primarily with the 57 cases.

OBSERVATIONS

Clinical. Table I shows the age distribution of the series.

The data reveal a predominance of women in a ratio of a little more than 2 to 1 with an

Left 2	—	4
Not separated as to side —	—	8

None of the patients had thyrotoxicosis. Two patients at the time of hospital entry had an elevated basal metabolic rate but displayed no other objective manifestations of a hyperfunctioning thyroid.

The lateral cervical masses. The lateral cervical masses which were excised and which were regarded clinically as aberrant thyroid tumors turned out to be one or more of the following: (1) neoplasm of thyroid tissue; (2) lymph node or nodes partially replaced by tumor; (3) negative lymph nodes. The histologic criteria of lymph nodes, especially those that were almost completely replaced by tumor, were a fibrous capsule, peripheral lymphoid follicles with germinal centers and sinuses (Figs 1, 2, 3). This combination of capsule, follicles, and sinuses was not seen in any of the tumors of the thyroid gland nor has it been found in other diseased thyroids except Hashimoto's struma along the capsular margin of the gland.

There were 17 cases in which the lateral masses microscopically consisted only of tu-

Fig. 1. Lymph node partially replaced by tumor. $\times 30$.

mor. In these instances the extirpated tumors showed no evidence of nodal structure in any portion nor was there any evidence as to their source, i.e., whether they arose from embryonal rests or from negative thyroid tissue. The number isolated in the laboratory ranged from 1 to 12 (Table III). In short, if the lateral tumors in these cases originated from defective embryogenesis or from a metastasis from the thyroid, there were no histologic findings to prove either derivation.

In 4 cases the lateral masses consisted of

average at admission for the entire series of 34.7 years. In the general thyroid material at this institution the ratio of women to men is 4:1 and the average age at admission of the surgical thyroid patient is 43.0 years, $7\frac{1}{2}$ years more than the average of this series. Almost two-thirds of the patients of this series are below the age of 40.

Table II presents the pretreatment interval. Here it is worthy of mention that a patient waited on the average almost 4 years (average duration 3.9 years) before seeking treatment and that 3 patients had histories of over 10 years. No correlation between the age of the patient and the duration of the history was disclosed.

The majority of patients had but one complaint: a lump, nodule or swelling in the neck which gradually enlarged. Forty three of the 57 patients offered this as a primary symptom and of these 37 had no other symptoms. In 4 instances the presence of a cervical mass was not noted by the patient and was discovered by the examining physician. Other symptoms consisted of a pressing or choking sensation, fatigue, dyspnea, local pain or tenderness. Signs rarely found were weight loss and voice change. When secondary symptoms and signs were present they usually occurred several weeks or months before the patient sought medical aid and were effective in forcing patient to find relief.

that in 45 of the 57 cases cervical masses were lymph nodes or containing tumor tissue when the material was available, that there were no gradations existing ranging from lymph nodes to partially replaced masses which could not be distinguished as nodal tissue.

The number of lateral masses was variable, ranging from 0.5 centimeter in diameter to 5 centimeters in diameter. There was no relation between the number and size of lymph nodes containing tumor or the duration in the neck as far as the duration was stated.

The position of the cervical masses was variable. They were seen most frequently extending from mastoid process to the sternum; they were also anterior to the sternocleidomastoid muscle posterior to the sternocleidomastoid muscle lateral to the trachea in the neck in the submaxillary region laterally and at the angle of the neck. They were on the right side 14 times, on the left side 23 times, bilateral 7 times, position not stated 3 times. In 14 cases studied histologically the tumor was as follows: malignant papillary adenocarcinoma in 13, adenocarcinoma in 14,

Fig. 7. Area of adenocarcinoma of thyroid tumor. Same case as shown in Figure 6. $\times 5$.

papillary adenocarcinoma in 6 and carcinoma simplex in 4.

The thyroid gland. In 49 cases the thyroid gland contained a tumor. In every instance

Fig. 8. Area of carcinoma simplex of thyroid tumor. Same case as shown in Figure 6. $\times 5$.

Fig. 3. Lymph node with lymphatic invasion by tumor. $\times 20$.

both tumor masses and lymph nodes containing tumor. There were 12 cases in which the cervical masses were tumor nodules, lymph nodes partially replaced by tumor, and negative lymph nodes. There were 4 cases in which the masses were only lymph nodes containing tumor, 14 cases in which the masses were both tumor and negative lymph nodes, 4 cases in which the masses were lymph nodes, either partially replaced by tumor or uninvolved

and 1 case in which the masses received in the laboratory were merely negative lymph nodes. This last patient had had a previous operation elsewhere with removal of a lateral mass and the diagnosis of thyroid neoplasm was confirmed in this laboratory by examination of the slides (Case 5).

Table III is a tabulation of these data and shows the pathology of the lateral cervical masses.

Fig. 4. Nodule of adenocarcinoma in thyroid gland. $\times 50$.

Fig. 5. Malignant papillary cystadenoma in lateral cervical mass. Same case as shown in Figure 4. $\times 75$.

Fig 6. Papillary area of thyroid tumor $\times 75$

Table III reveals that in 45 of the 57 cases some of the lateral cervical masses were lymph nodes either uninvolved or containing tumor. It was apparent also when the material was examined microscopically that there were many cases in which gradations existed ranging from negative lymph nodes to partially replaced nodes to masses which could not be certainly recognized as nodal tissue.

The average number of lateral masses was six. Their size ranged from 0.5 centimeter in diameter to 8 centimeters in diameter, most being about 1.5 centimeters in diameter. There was no correlation between the number and size of tumor masses or lymph nodes containing tumor and their duration in the neck as disclosed by history.

The location of the cervical masses was variable and widespread. They were seen most often as a chain extending from mastoid process to clavicle but they were also anterior to the sternocleidomastoid muscle posterior to the sternocleidomastoid muscle lateral to the great vessels of the neck in the submaxillary triangle subinternally and at the angle of the jaw as a single tumor. They were on the right side 23 times on the left side 23 times bilateral 8 times and position not stated 3 times.

In the 57 cases studied histologically the diagnoses were as follows: malignant papillary cystadenoma in 33, adenocarcinoma in 14,

Fig 7. Area of adenocarcinoma of thyroid tumor. Same case as shown in Figure 6 $\times 75$

papillary adenocarcinoma in 6 and carcinoma simplex in 4.

The thyroid gland. In 49 cases the thyroid gland contained a tumor. In every instance

Fig 8. Area of carcinoma simplex of thyroid tumor. Same case as shown in Figures 6 and 7 $\times 75$

Fig. 9. Typical malignant papillary cystadenoma. X30

the thyroid neoplasm was malignant and in all but 1 case was histologically identical with the lateral masses. In this latter patient there was an adenocarcinoma of the thyroid gland while the cervical masses presented a malignant papillary cystadenoma (Figs. 4 and 5).

There were 8 cases of the 57 in which a cancer of the thyroid was not found. Of these the glands of 4 patients were not removed having been regarded as negative at operation. In the remaining 4 cases the thyroids had been previously removed elsewhere and were not available for study.

Almost 15 per cent of the series were clinically free of thyroid disease though neoplasm was revealed at operation or in the laboratory. At the physical examination the thyroid was stated to be negative in 5 instances yet at operation a neoplasm was found larger than 1 centimeter in diameter. In 3 cases the gland was neither mentioned nor described in the history and a tumor was disclosed at operation. There was 1 case in which the thyroid after palpation at operation was stated to be negative. A tumor however less than 0.5 centimeter in diameter was discovered in the pathological laboratory. This was the only time a tumor was found in the thyroid less than 1 centimeter in diameter.

Precise anatomical location of the neoplasm in the thyroid was described in 18 cases. A

superior pole alone was involved in 7 cases. An inferior pole alone was involved in 5 cases. A single discrete nodule was present in both lobes or in one lobe and the isthmus in 4 instances. And in 1 patient there were two distinct tumor nodules in a single lobe. The remaining 31 patients were either not examined for location of the neoplasm or were diffusely affected throughout one or both lobes.

A comparison between the size of the thyroid tumor and the size of the lateral masses could not be made for in many instances the thyroid malignancy was not carefully measured. There were, nevertheless, at least 3 cases in which a single cervical mass was known to be larger than the tumor in the thyroid. In 41 cases in which there was a neoplasm of one lobe the affected lobe and the lateral cervical masses were on the same side. There were 7 instances in which both lobes contained a neoplasm and 1 instance in which a lobe and the isthmus were involved. In these latter cases there were bilateral cervical masses present.

Histology The histology of the lateral masses and thyroid tumors was quite pleomorphic, but except for 1 case the neoplasms in the thyroid gland and the lateral masses were histologically identical. Table IV lists the microscopic classification of the tumors, including the 8 cases in which only the lateral masses were available.

Fig 10 Squamous metaplasia in malignant papillary cystadenoma. $\times 120$

These diagnoses were based on the predominant pattern of growth revealed in microscopic section. The patterns were markedly variable (Figs 6 7 8). In almost every instance individual microscopic fields could be found which showed negative-appearing follicles fetal thyroid tissue complex arborescent fronds adenocarcinoma and carcinoma simplex. Generally however a single pattern predominated and this was usually of a papillary nature (Figs 9 and 10). Thirteen of the 14 cases of adenocarcinoma exhibited scattered minute regions of papillary structure. For the most part the neoplasms were well differentiated showing slight to moderate neoplasia and rare mitoses. Calcific concretions were seen 53 times being present in all tumors of the first three classifications. Ossification was present in 1 malignant papillary cystadenoma (Fig 11). In 2 instances the neoplastic tissue deviated so little cytologically from the normal that malignancy would not be suspected except for the fact that thyroid acini formed tu-

mor emboli in one (Fig 12) and were in the corium of the skin in the other case.

The cytological changes of malignancy were frequently difficult to evaluate for epithelial alteration was often slight. But generally the epithelium showed definite recognizable differences from the epithelium of normal hyperplastic or nodular goitrous thyroid. When found the changes were the same as those which characterize malignancy anywhere else in the body.

More obvious than the cytologic changes were the invasive properties. The latter included blood vessel lymphatic and invasion of surrounding tissue. True intravascular invasion was accepted only if thyroid epithelium formed part of a thrombus or embolus within a fibromuscular wall lined with endothelium and having an elastic lamina or if the

Fig. Blood vessel invasion. Not negative appearing thyroid follicles and lack of cytological alteration. $\times 75$

epithelium was attached to such a wall (Fig. 13). Lymphatic invasion was represented by the presence of tumor within at least three endothelial-lined spaces at a distance from the cut edge of the section (Fig. 14). Invasion of adjacent tissue was considered present if there was actual infiltration of capsule of negative-appearing thyroid parenchyma or of both (Fig. 15).

With these criteria it was found that the 49 cases in which the thyroid was available showed

one or more of the above invasive properties in the sections taken from the thyroid tumor. Occasionally the lateral neoplasms of these cases exhibited intravascular or lymphatic infiltration but this was noted less frequently than in the material from the thyroid gland. The data are given in Table V.

There were 8 patients from whom only the lateral cervical masses were resected. The thyroid was removed elsewhere in 4 instances and in 4 instances no resection was done be-

Fig 13. Blood vessel invasion $\times 75$

cause the gland was negative at operation. In 5 of these 8 cases the lateral masses showed invasive characteristics and were either lymph nodes partially replaced or solely tumor tissue not identifiable as being in lymph nodes. In 2 cases no invasive features were exhibited and the masses consisted entirely of neoplastic tissue. In the last case the cervical masses were 8 negative lymph nodes, no tumor being present (Case 5).

Outcome. Follow up observations are not available for most of the patients. For 9 there are partial data concerning outcome of treat-

ment. Of these there were local recurrences in 8 patients with subsequent death of 1. The ninth patient with a malignant papillary cyst adenoma was admitted to the hospital for cardiovascular renal disease 10 years after a radical neck dissection. At this time he was clinically free of thyroid malignancy. The patient who died suffered four local recurrences over a period of 11 years and finally succumbed following a craniotomy for removal of thyroid metastases to skull and brain (Fig 16). Her tumor at first cytologically resembled negative-appearing thyroid tissue (mentioned before

Fig 14. Lymphatic invasion present at a distance from cut edge of the section. $\times 180$.Fig 15. Simple invasion of thyroid gland by tumor $\times 30$.

Fig. 6. Metastasis of thyroid carcinoma to skull bone. $\times 245$

under histology) but it later assumed in the course of her disease the histologic features of an adenocarcinoma. One patient with a malignant papillary cystadenoma suffered a recurrence 1 $\frac{2}{3}$ years after her operation. Another with the same type of neoplasm experi-

enced 2 recurrences over a 2 year period. One patient with an adenocarcinoma had a local recurrence after 1 $\frac{3}{4}$ years. A second with the same type of tumor had a recurrence 2 years after surgical treatment. A third patient with an adenocarcinoma suffered a recurrence 7 $\frac{1}{2}$ years following her first operation. There was a papillary adenocarcinoma which recurred twice over a 6 $\frac{3}{4}$ year period. The last patient with a carcinoma simplex experienced 3 recurrences over a 14 year period. The final status of these 7 patients is unknown.

TABLE VI

Type of tumor	No. of recurrences or metastases	Time interval, years	Site of recurrence or metastases
Malignant papillary cystadenoma	—	$\frac{1}{3}$	Neck, on same side as thyroid tumor
Adenocarcinoma	—	—	Neck, on side opposite to thyroid tumor
	—	—	Neck, same side as thyroid tumor
	—	—	Neck, same side as thyroid tumor
	—	—	Neck, same side as thyroid tumor
	—	—	1st recurrence in neck on side opposite to original tumor, and 2nd recurrence in neck in laterality; 3rd recurrence in skull as metastases
Papillary adenocarcinoma	—	—	Neck, both on side opposite to thyroid tumor
Carcinoma simplex	—	—	1st recurrence in neck, side opposite to original tumor, and recurrence in neck, on same side as original tumor, and recurrence in larynx with fixation of trachea

ILLUSTRATIVE CASE REPORTS

CASE 1. Typical case. A 33 year old woman had a slowly enlarging mass in the right side of her neck for 10 years. There were no other symptoms. Examination disclosed a 2 by 4 centimeter nodule in the right neck, anterior to the sternocleidomastoid muscle just above the level of the thyroid. The thyroid was negative to palpation. At operation several masses were found in the right neck and the right lobe of the thyroid was the site of malignant change. A block dissection was done. In the laboratory a malignant papillary cystadenoma of the thyroid was found microscopically. There were also 7 lymph nodes isolated including the nodule described. Two of these were partially replaced by the same type of neoplasm.

CASE 2. Local recurrences. A 34 year old woman noticed a mass in left side of her neck for 3 years which fluctuated in size. Two months before admission she experienced a choking spell and was found to have a recurrent laryngeal nerve paralysis. A biopsy

elsewhere from one of the cervical masses revealed thyroid adenocarcinoma. At operation numerous "aberrant" nodules were present on both sides of the neck, extending from the upper neck into the mediastinum. The entire thyroid was diffusely enlarged. Aberrant tissue had invaded the carotid sheath and pretracheal fascia. In two stages a left total hemithyroidectomy and radical dissection of left side of neck was done followed by a right total hemithyroidectomy and partial neck dissection. Microscopically there was a well differentiated adenocarcinoma in the thyroid. Of 5 nodules isolated from the right side 4 were lymph nodes partially replaced by cancer and the fifth was composed entirely of tumor tissue. Of 5 nodules isolated from the left side 3 were negative lymph nodes and 2 contained metastases. Blood vessel, lymphatic, and stromal invasion were marked.

Twenty months later after several series of x ray treatments the patient was reoperated upon because of recurrence about the trachea. Eight months after this procedure she was treated with surgery for a third time because of local recurrence. Microscopic sections of tissue removed at these operations revealed the same tumor as was originally seen. The final status of the patient is unknown.

CASE 3. Data insufficient for final diagnosis. A 43 year old woman was admitted to the hospital because of a lump in her neck. Seven years before she had had a left hemithyroidectomy for Graves disease and 5 years before had a partial thyroidectomy also because of thyrotoxicosis. Four years after the second operation a nodule developed in her neck, which proved to be thyroid tissue. Two months before admission a second mass appeared to the right of the thyroid cartilage. There were no other symptoms. At operation numerous nodules were found about the right internal jugular vein which had to be divided. The thyroid region was not examined. Pathological reports on the tissue previously removed were not available. At the present pathological examination 11 nodules were isolated. Of these one was a negative lymph node 4 were nodes partially invaded by thyroid neoplasm and the remaining were thyroid neoplastic tissue not identifiable as lymph nodes. Histologically the tumor was pleomorphic but predominantly a malignant papillary cystadenoma.

CASE 4. True ectopic thyroid. A 49 year old woman had a thyroidectomy 30 years ago. 11 years after the operation a lump appeared in right side of neck and slowly enlarged. There were no other symptoms. At operation 19 years after the appearance of the cervical mass a tumor 2 centimeters in diameter was located beneath the skin just at the tip of the old scar. The thyroid remnants on the right side were negative to palpation. Microscopically the excised tissue showed the histology of a fetal adenoma, completely encapsulated and exhibiting no evidence of invasiveness or cytologic malignancy.

CASE 5. Tumor of thyroid and lateral cervical mass removed elsewhere. A 7 year old boy was operated

upon at another hospital where an encapsulated mass was excised from the thyroid gland and another mass removed from the left side of the neck. The microscopic diagnosis was adenocarcinoma which was confirmed by Dr. Shields Warren. Two months later he was admitted to this institution for an exploration of his neck and for advice as to future management. At operation the thyroid appeared to be negative. Eight small nodules located along the course of the internal jugular vein bilaterally and thought to be aberrant thyroid tissue were excised. The thyroid was not removed. Microscopically the 8 nodules were lymph nodes.

DISCUSSION

Numerous pitfalls beset the study of aberrant thyroid tissue. First it is obvious that many of the early case reports were incomplete (1 9 23 24 26 29 33 35). Excision of lateral masses was accomplished without inspection or palpation of the thyroid before or during operation. Furthermore clinical and operative examinations of the gland were often inadequate. In this series almost 15 per cent of the cancers of the thyroid gland were not palpated before operation and one was missed during the surgical procedure only to be discovered in the laboratory. In more recent years as the thyroid has been examined more closely or removed at operation for lateral aberrant thyroids more and more neoplasms have been found (2 3 4 7 10 12 19 22 37). Crile has particularly pointed out that thyroid cancer was occasionally not perceived until the gland was lifted from its bed and its posterior surface studied (8).

A second pitfall exists because of the confusion between lateral thyroid neoplasms as observed in this paper and ectopic fragments of thyroid tissue found occasionally at autopsy or rarely during thyroidectomies. The latter masses are not true tumors and are of two types. One type is an encapsulated fragment of tissue usually measuring between 3 to 5 millimeters in diameter which though completely separated from the gland is directly contiguous with the capsule. Histologically it is composed of a normal thyroid architecture. Other larger masses comprise the second type are found in the mediastinum or supraclavicular regions and are associated with enlarged adenomatous thyroids which have endured longstanding disease. Histologically these show

Fig. 6 Metastasis of thyroid carcinoma to skull bone. X245

under histology) but it later assumed in the course of her disease the histologic features of an adenocarcinoma. One patient with a malignant papillary cystadenoma suffered a recurrence 12½ years after her operation. Another with the same type of neoplasm exper-

enced 2 recurrences over a 2 year period. One patient with an adenocarcinoma had a local recurrence after 12½ years. A second with the same type of tumor had a recurrence 2 years after surgical treatment. A third patient with an adenocarcinoma suffered a recurrence 7½ years following her first operation. There was a papillary adenocarcinoma which recurred twice over a 6½ year period. The last patient with a carcinoma simplex experienced 3 recurrences over a 14 year period. The final status of these 7 patients is unknown.

TABLE VI

Type of tumor	N. of recurrences or metastases	Time (interval) yrs.	Site of recurrence or metastases
Malignant papillary			Neck, on same side as thyroid tumor
Cystadenoma			Neck, on side opposite to thyroid tumor
Adenocarcinoma			Neck, same side as thyroid tumor
			Neck, same side as thyroid tumor
			Neck, same side as thyroid tumor
			1st recurrences in neck on side opposite to original tumor, 2nd and 3rd recurrences in neck laterally, 4th recurrence in skull as metastases
Papillary adenocarcinoma			Neck, both on side opposite to thyroid tumor
Carcinoma simplex			1st recurrence in neck, side opposite to original tumor, 2nd recurrence neck, on same side as original tumor, 3rd recurrence infiltration of trachea

ILLUSTRATIVE CASE REPORTS

CASE 1. Typical case. A 23 year old woman had a slowly enlarging mass in the right side of her neck for 6 years. There were no other symptoms. Examination disclosed a 2 by 4 centimeter nodule in the right neck, anterior to the sternocleidomastoid muscle just above the level of the thyroid. The thyroid was negative to palpation. At operation several masses were found in the right neck and the right lobe of the thyroid was the site of malignant change. A block dissection was done. In the laboratory a malignant papillary cystadenoma of the thyroid was found microscopically. There were also 7 lymph nodes isolated, including the nodule described. Two of these were partially replaced by the same type of neoplasm.

CASE 2. Local recurrences. A 34 year old woman noticed a mass in left side of her neck for 3 years which fluctuated in size. Two months before admission she experienced a choking spell and was found to have a recurrent laryngeal nerve paralysis. A biopsy

There were no other symptoms. At operation 19 years after the appearance of the cervical mass a tumor 2 centimeters in diameter was located beneath the skin just at the tip of the old scar. The thyroid remnants on the right side were negative to palpation. Microscopically the excised tissue showed the histology of a fetal adenoma, completely encapsulated and exhibiting no evidence of invasiveness or cytologic malignancy.

CASE 5. Tumor of thyroid and lateral cervical mass removed elsewhere. A 7 year old boy was operated

upon at another hospital where an encapsulated mass was excised from the thyroid gland and another mass removed from the left side of the neck. The microscopic diagnosis was adenocarcinoma which was confirmed by Dr. Shields Warren. Two months later he was admitted to this institution for an exploration of his neck, and for advice as to future management. At operation the thyroid appeared to be negative. Eight small nodules located along the course of the internal jugular vein bilaterally and thought to be aberrant thyroid tissue were excised. The thyroid was not removed. Microscopically the 8 nodules were lymph nodes.

DISCUSSION

Numerous pitfalls beset the study of 'aberrant' thyroid tissue. First it is obvious that many of the early case reports were incomplete (1, 9, 23, 24, 26, 29, 33, 35). Excision of lateral masses was accomplished without inspection or palpation of the thyroid before or during operation. Furthermore, clinical and operative examinations of the gland were often inadequate. In this series almost 15 per cent of the cancers of the thyroid gland were not palpated before operation and one was missed during the surgical procedure, only to be discovered in the laboratory. In more recent years, as the thyroid has been examined more closely or removed at operation for 'lateral aberrant thyroids' more and more neoplasms have been found (2, 3, 4, 7, 10, 12, 19, 22, 37). Crile has particularly pointed out that thyroid cancer was occasionally not perceived until the gland was lifted from its bed and its posterior surface studied (8).

A second pitfall exists because of the confusion between lateral thyroid neoplasms as observed in this paper and ectopic fragments of thyroid tissue found occasionally at autopsy, or rarely during thyroidectomies. The latter masses are not true tumors and are of two types. One type is an encapsulated fragment of tissue usually measuring between 3 to 5 millimeters in diameter, which, though completely separated from the gland, is directly contiguous with the capsule. Histologically it is composed of a normal thyroid architecture. Other larger masses comprise the second type, are found in the mediastinum or suprasternal regions and are associated with enlarged adenomatous thyroids which have endured longstanding disease. Histologically these show

a colloid adenomatous structure. Pemberton suggests they are pinched off from the thyroid gland by scarring (18). Four such cases were mentioned early in this paper but were not included in the analysis because they did not form true tumors in the lateral aspects of the neck.

A third pitfall is related to the peculiarities of thyroid tissue biologically and cytologically. The patterns of growth in diseased glands are amazingly variable and especially is this true for the low grade thyroid malignancies. Graham demonstrated long ago that portions of thyroid cancers can mimic microscopically the entire gamut of cellular change found in non-neoplastic disease (13, 14). He insisted and this series reaffirms it, that the important signs of malignancy are the invasive features. Since morphologic alteration is so slight, pathologists in the past have often not recognized thyroid cancer. Biologically also the low grade thyroid cancers especially those with papillary structures, are slow-growing and tend to cause death late. Numerous documented case reports only now being described in the medical literature attest to this phenomenon (5, 8, 12, 18). The growth and expansion of these tumors should more often be measured in decades rather than years. Moreover, metastases may outgrow in size the original tumor and may proliferate for long periods before causing death. Previous to 10 years ago the reported cases were insufficiently followed and the complete history of them had not been traced to the end.

A final pitfall of the subject is concerned with lymphoid tissue. Thyroid glands diseased for long periods of time be they of the hyperplastic or nontoxic adenomatous types tend to accumulate lymphoid tissue and even well formed follicles. In addition embryologists have noted the development of lymphoid aggregates about differentiating cell clusters derived from various branchial pouches. Hence, many authors feel that the presence of lymphoid tissue in and around thyroid tissue does not signify a lymph node. But lymphoid stroma in diseased thyroids do not reduplicate the architecture of a node, for sinuses are lacking. The histologic picture of thyroid neoplasm surrounded partly or wholly by a fibrous

capsule, a row of follicles with germinal centers and sinuses can usually be recognized as a metastasis to a lymph node. Rarely is the combination of capsule follicles and sinuses found in diseased thyroids and then only in Hashimoto's struma.

After anatomists noted ectopic thyroid nodules in the neck (15, 16) and after embryologists described the genesis of the gland (17) it was an easy and logical step to postulate a theory of embryonal rests. To this assumption there have been several additions. Schrager hypothesized that the embryonal rests were 'inferior' thyroid tissue and that they enlarged when demands upon the thyroid became excessive. Others felt that embryonal rests were prone to become neoplastic and then metastasize to the thyroid and regional lymph nodes (2, 3, 12, 22). Cohn and Stewart, in order to explain the presence of tumor in the thyroid gland as well as in the lateral neck, theorized that in some cases the lateral primordium retained its identity after fusion with median anlage of the fetal thyroid.

These theories are inadequate to explain the many facets of the problem. First it is agreed among embryologists that cell aggregates from the fourth branchial pouch fuse with the median anlage of the fetal thyroid. Beyond this there is no agreement. Kingsbury maintained that the lateral primordia degenerated after fusion (20, 21) while Norris and Weller stated that the fourth pouch contributed functioning thyroid follicles to the gland (27, 28, 36). Second there is no morphological or physiological evidence for 'inferior' thyroid tissue. 'Lateral aberrant thyroid tissue is neoplastic and does not resemble normal hyperplastic, or adenomatous thyroid tissue. Nor do patients with cervical masses of thyroid tissue exhibit thyrotoxicosis to suggest increased stress upon the thyroid. Third Mahorner and associates have demonstrated that the lymphatics of the thyroid carry away from the organ. Fourth, if it is conceded that the lateral primordia form functioning thyroid tissue, and if Norris and Weller are correct in stating that they form the upper poles of the two lobes, then neoplasms in the gland derived from rests, should arise in the upper poles. In the present series cancer was present in the in-

terior pole alone at least five times and in the isthmus once

If lateral aberrant thyroids are a result of defective embryogenesis, then occasionally at least, thyroid remnants and tumors should be found in branchial cleft cysts which represent anomalous development of one or more branchial pouches. Among 113 branchial cleft cysts operated on in this institution only 3 tumors were found and none of these was composed of thyroid tissue. Crile and Kearns described only epidermoid carcinoma in 28 branchial tumors (6). Nor are remnants of thyroid tissue seen in branchial cleft defects.

On the other hand median aberrant thyroid tissue is often associated with thyroglossal duct cysts (30). The thyroglossal duct is derived from the development of the median anlage, which grows out of the pharyngeal pouch. Collections of thyroid acini were present 77 times among 190 patients operated upon here for this fetal anomaly (11). It is noteworthy that lateral aberrant thyroid tumors have not shown similar clusters of thyroid acini nor have the lateral neoplasms been discovered developing from such thyroid follicles.

As for the distribution of the cervical masses it is too widespread to be contained within the tract of the migrating fourth pouch. The lateral tumors have been found external to the carotid artery subinternally at the mastoid process and in the submaxillary triangle sites which are beyond the anatomic wanderings of the primordial lateral thyroid.

Finally there is a marked similarity between the so-called lateral aberrant thyroid tumors and the malignant papillary cystadenomas of the thyroid gland. They resemble each other in age and sex distribution in length of the pretreatment interval, in their histology biologic and final outcome. An analysis of 120 malignant papillary cystadenomas in our laboratory revealed no essential difference from the lateral aberrant tumors with the one exception that the latter were discovered clinically before the presence of a cancer in the thyroid was noted (11). A comparison with Pemberton's data on papillary carcinomas of the thyroid also disclosed the similarity between the lateral cervical tumors and papillary

neoplasms. His and our data show that the histological, biological, and clinical features of the two groups are the same (31, 32).

Our data indicate that lateral thyroid tumors of the neck are metastases from cancers of the thyroid. This is supported by the following: (1) all thyroid glands received in the laboratory contained a tumor which was histologically identical with the neoplasms in the lateral neck; (2) in the majority of cases some of the lateral masses clinically regarded as aberrant thyroid tissue were either lymph nodes partially replaced by tumor or uninvolvement (3) the distribution in the neck of the lateral masses was the same as the anatomical disposition of cervical lymph nodes; (4) the characteristics of these lateral tumors were the same as the low-grade papillary carcinomas of the thyroid; (5) study of branchial cleft cysts and thyroglossal ducts embryologic anomalies associated with thyroid development revealed no evidence that lateral aberrant thyroid tumors develop from embryonal rests.

SUMMARY

1. An analysis was made in 57 cases clinically diagnosed lateral aberrant thyroid tumors. Six other cases were not included because they proved not to be tumors on histologic examination.

2. In 49 of the 57 cases there was an associated thyroid cancer. 15 per cent of these were not detected clinically. In the remaining 8 cases the thyroid gland was not received in the laboratory either because they were removed elsewhere or because they were regarded as uninvolved by tumor at operation.

3. The histology of the tumor in the thyroid and in the lateral masses of the neck was identical in all but 1 instance. It was usually papillary in structure though the neoplastic growth patterns were markedly pleomorphic.

4. In 40 of the 57 cases the lateral tumors were found to be metastases to cervical lymph nodes. In the remaining 17 cases there was no microscopic evidence that the lateral tumors were either metastatic or derived from embryonal rests.

5. These neoplasms tend to occur in a younger age group than does cancer in general.

or than does thyroid disease. The presenting finding is usually only a swelling or nodule in the neck, with an average pretreatment interval of almost 4 years.

6 The disease often recurs locally unless completely eradicated by surgery. Follow up observations must be made over decades rather than years.

7 The data indicate that most if not all lateral thyroid tumors of the neck are metastases from cancers of the thyroid.

EVALUATION OF SKIN GRAFTING IN THE TECHNIQUE OF RADICAL MASTECTOMY IN RELATION TO LOCAL RECURRENCE OF CARCINOMA

HERBERT CONWAY M.D., and CHARLES G NEUMANN M.D., New York, New York

THE percentage of patients alive and free from recurrence or metastasis 5 years after operation is the common measure of the effectiveness of radical mastectomy in the treatment of carcinoma of the breast. In the course of the years since the Halsted technique of radical mastectomy was established, the percentage of 5 year cures has increased progressively. Although the basic principles of the technique of operation as developed by Halsted are in use in many clinics throughout this country certain variations have been developed. These variations concern the type of incision and the amount of mammary skin which is removed. While subcutaneous tissues and musculature may be excised freely from the thoracic area, the necessity for wound closure restrains the surgeon in the excision of wide margins of skin. The introduction by Halsted of the use of skin grafting made radical excision of skin a more feasible step. Still there is active dispute concerning the amount of skin which should be removed in conjunction with a given tumor. The opinion has been expressed that only by wider excision of skin can local recurrence be made less frequent and the percentage of 5 year cures increased. In an attempt to come to an understanding of the relative value of the wide removal of skin the case records of patients subjected to radical mastectomy at The New York Hospital have been reviewed. In this analysis attention has been given to the relation of the use of a skin graft to the occurrence of local recurrence and to the rate of local recurrence as an indicator of the development of widespread metastases.

The basis of this study is the 255 patients on whom radical mastectomy was performed for carcinoma of the breast from September 1 1932 to September 1 1942. The shortest period of follow up is 5 years. Operative surgery in these cases was done by 15 different surgeons most of whom served as resident surgeon at the time. The basic steps of radical mastectomy followed the technique of Halsted (1) preliminary biopsy with microscopic examination to ascertain the nature of the lesion (2) preparation of the skin of the thigh as the donor site for a thick-split graft of skin (3) use of a circular or elliptical incision about the tumor at a distance of at least 5 centimeters from its palpable margin (4) extension of the incision from its central ellipse superiorly to the middle or lateral third of the clavicle and inferiorly to the costal margin (5) reflection of flaps of skin and a small amount of subcutaneous tissue superiorly to the clavicle medially to the mid sternum inferiorly to a point below the costal margin and laterally to the border of the latissimus dorsi muscle and the humeral insertion of the pectoralis major muscle (6) detachment of the pectoralis major and minor muscles and their fasciae from their origins on the chest wall and their insertions into the humerus and coracoid process (7) complete dissection of the axillary vein to permit removal of all of the contents of the axilla including lymphatic vessels and glands adipose and areolar tissue (8) removal of breast axillary contents pectoralis major and minor muscles en masse (9) reconstruction of a high axilla by obliteration of dead space and suture of the upper and outer cutaneous flap to the chest wall immediately posterior and inferior to the axillary vein (10) suture of the margins of the cutaneous flaps superior to, medial to and inferior to a central defect on the chest wall (suture is effected without undue tension while the arm is held in abduction at an angle of 90 degrees) (11) application of a thick

split graft to the residual open wound on the chest wall and (12) application of a suitable dressing to maintain pressure upon the graft and the flap and to immobilize the arm in slight abduction.

Local recurrence of tumor developed in 44 (17 per cent) of the 255 patients. This was in general agreement with the reports of the surgeons who advocate the use of skin grafts in the closure of the wound of the chest wall and yet represented a higher percentage of recurrence than reported by surgeons who tend to avoid the use of skin grafts. Accordingly the cases were divided into two groups on the basis of the use of a graft. This separation of cases showed that contrary to expectation the rate of local recurrence was considerably higher in patients in whom the wounds were closed with a graft than in those in whom closure of wounds was by primary suture of the margins of the flaps. There was local recurrence in 40 (21 per cent) of 188 cases in which a graft was employed. In 67 cases in which the wounds were closed without a graft there were recurrences in only 4 (6 per cent) (Table I). Because of the possibility that grafting had been used more frequently following the extirpation of large tumors and

that this fact might account for the high rate of recurrence, attention was directed to the study of the size of the tumor in relation to the type of closure. Attention was also given to the presence or the absence of axillary metastases.

The patients were divided into four groups on the basis of the diameter of the primary lesion as measured before operation. Also the patients were divided into two groups on the basis of the presence and absence of axillary metastases. Since the surgeon is called upon to complete the radical mastectomy without accurate information as to the histopathology of the tumor and its relative malignancy this study has concentrated on evaluation of the operative steps which are under control at the time of operation.

Review of the cases in which the tumor was small showed that grafts were used in closure of the wounds in 70 per cent of the cases. For the largest tumors as one might expect grafts were used in a higher percentage of cases in this series 87 per cent. For the purpose of ascertaining the relationship of grafting to local recurrence attention is devoted to the smaller tumors. Of the 154 cases in which wounds were closed with a graft local recurrence developed in 24 instances (16 per cent). Of the 62 cases in which wounds were closed without a graft local recurrence developed in only 4 (6 per cent) (Table II). In the group of patients with larger tumors local recurrence occurred in 16 of 34 patients whose wounds were closed with a graft whereas no local recurrences developed in 5 patients whose wounds were closed without a graft (Table II). Thus the evidence on analysis of the small tumors foreshadows that of the large tumors. The use of grafting in the closure of the wound after a radical mastectomy has been performed is associated with a higher incidence of local recurrence.

In the development of local recurrence following radical mastectomy the presence of axillary metastasis at the time of operation is a factor of importance. Of the 107 patients with axillary metastases and in whom the wounds were closed with grafts 27 (25 per cent) developed local recurrence. Of the 81 patients without axillary metastases and with

TABLE II.—ANALYSIS OF USE OF THICK SPLIT GRAFTS IN RELATION TO SIZE OF TUMOR

wounds closed with grafts recurrence was noticed in only 13 (16 per cent) (Table I). The number of local recurrences in patients whose wounds were closed without a graft was too small to warrant conclusions. However it is recorded that there were recurrences in 2 of 32 patients with axillary metastasis and recurrences in 2 of 35 patients without axillary metastasis (Table I).

Because of this evidence that axillary metastases predispose to a high percentage of local recurrence it became necessary to cull from the available data the number of cases of axillary metastasis in which the wounds had been closed by skin grafts. Fifty seven per cent of the 188 patients with grafts had axillary metastasis whereas 48 per cent of the 67 patients without grafts had this complication (Table I). This difference is not great enough to parallel the comparative incidence of local recurrence in the two types of cases.

The size of the tumor at the time of operation had an important bearing on the incidence of local recurrence. This can be demonstrated in the patients with and without axillary metastasis. In the very small tumors, the rate of local recurrence was 4 per cent, whereas in the largest tumors, the rate of local recurrence approached 50 per cent (Table I).

The importance of local recurrence as a prognostic sign may be demonstrated by reference to Table III. Of the 255 cases studied, 125 patients (49 per cent) survived more than 5 years and in this group the rate of local recurrence was only 1.6 per cent. One hundred and thirty patients survived less than 5 years and in this group there were 42 local recurrences a rate of 32 per cent. Seven local recurrences developed in 23 patients surviving less than 1 year (30 per cent). 24 in 72 patients surviving 1 to 3 years (33 per cent)

and 11 in 35 patients surviving 3 to 5 years (31 per cent). Thus it may be stated that the development of local recurrence is almost positive assurance that death will occur within 5 years of operation. Thus local recurrence assumes an importance far beyond that of axillary metastasis for 32 per cent of patients with axillary metastasis survived beyond 5 years whereas only 1.6 per cent of patients with local recurrence did so. Although local recurrence is of grave prognostic significance it is not at all clear whether local recurrence predisposes to or is merely a sign of general metastatic spread. Of the 44 local recurrences observed in the 255 cases under consideration 17 appeared before any clinically evident spread had occurred elsewhere, 12 appeared simultaneously with and 15 after general spread. When local recurrence appeared following grafting (40 instances) it was as a nodule or two in the immediate vicinity of the grafted area in 27 cases (67.5 per cent), within the grafted area in 6 cases (15 per cent) and as innumerable foci on the chest wall in 7 cases (17.5 per cent).

DISCUSSION

The fact that local recurrence was found commonly in the skin of the chest wall about the grafted area suggests that surgeons had not been radical enough in the sacrifice of skin. The directions given by many surgeons for the performance of radical mastectomy include an

TABLE III.—ANALYSIS OF LENGTH OF SURVIVAL IN RELATION TO LOCAL RECURRENCE

admonition to space the elliptical or oval incision of the skin at a specified distance from the palpable margins of the tumor. The dictum that the local lesion should be skirted by at least 5, 7, or even 9 centimeters does not it seems give due importance to the fact that the larger the tumor the more likely has it spread a greater distance from its palpable margin. Thus the suggestion is pertinent that the larger the tumor the more difficult it is to eradicate. Therefore if wide skin excision be practiced for a small tumor much wider excision must be practiced for the large tumor. Practice of this principle may make it possible to reduce the rate of local recurrence and to increase the percentage of 5 year survival. That it probably never will be possible to avoid local recurrence entirely is shown by the fact that approximately 32.5 per cent of local recurrences appear within the grafted area, or as very widespread and innumerable foci. These foci may very well result from retrograde extension from residual intercostal and internal mammary lymphatics. It is on the 70 per cent of local recurrences which appear as discrete nodules near the grafted area or line of closure that the surgeon must concentrate. Obviously it is impossible to set down the specific spot at which the scalpel should be placed for each size of tumor. However since the pectoral fascia, pectoral muscles and axillary contents may be thoroughly excised it would seem the logical next step to carry the proposals of Halsted, J. S. Rodman, Haagensen, Lewis and Rienhoff and Eggers de Cholnoky and Jessup one step farther and to excise proportionately more skin the larger the tumor rather than have a more or less fixed limit of cutaneous excision for tumors of variable size.

The only reason for failure to remove a very wide margin of skin is the surgeon's reluctance to have the patient left with a large defect on the chest wall. It is not new to call for wider removal of skin for Lewis and Rienhoff found cause to state in 1932 that surgeons showed a tendency toward less radical excision of skin

breast have been made the basis of a clinical evaluation of the relation of skin grafting to local recurrence and the importance of local recurrence in the course of carcinoma of the breast.

Local recurrence developed in 44 (17 per cent) of the group of 255 patients. In 188 cases in which a graft was employed in closure of the wound there were 40 instances of local recurrence (21 per cent) whereas in 67 cases of closure without a graft there were only 4 instances of local recurrence (6 per cent). Approximately 70 per cent of the closures of wounds following radical mastectomy made use of grafts regardless of whether the tumor was less than 3 centimeters in diameter, 3 to 5 centimeters in diameter or 5 to 7 centimeters in diameter. Following extirpation of tumors larger than 7 centimeters 87 per cent of wounds were closed with a skin graft. Axillary involvement was present with nearly equal frequency in those cases in which the wounds of mastectomy were closed with a graft (48 per cent) and in those closed without a graft (57 per cent).

The size of the tumor at the time of operation had an important bearing on the incidence of local recurrence. In tumors of the smallest size the rate of local recurrence was as low as 4 per cent whereas in the tumors of largest size, the rate of recurrence was found to approach 50 per cent.

Local recurrence had an important bearing on the length of survival following radical mastectomy. In the 125 patients surviving more than 5 years, local recurrence developed in 1.6 per cent, whereas in the 130 patients surviving less than 5 years, the rate of recurrence was 32 per cent.

Of the 40 instances of local recurrence following grafting, 27 (67.5 per cent) appeared as solitary nodules in the immediate vicinity of the graft whereas only 13 (32.5 per cent) appeared within the grafted area or as multiple metastases both surrounding and within the grafted area. This situation gives rise to the thought that more radical excision of skin might give further protection against local recurrence.

Since the rate of local recurrence seems to be very closely related to the size of tumor at

SUMMARY

The case records of 255 patients subjected to radical mastectomy for carcinoma of the

the time of operation it seems likely that local recurrence in the form of solitary nodules outside the area of grafting is related to insufficient removal of skin. The suggestion is therefore made that the excision of skin in radical mastectomy be more radical. With the improved methods of skin grafting now available, it seems indefensible that surgeons should not remove a truly wide area of skin at the time that radical mastectomy for carcinoma is carried out. The larger the tumor the greater the need for very wide excision of skin.

THE OBSTRUCTED UTERINE CERVIX

GEORGE F MELODY M.D., San Francisco, California

NO pathological entity in the practice of obstetrics and gynecology is capable of more diverse manifestations than obstructive lesions of the uterine cervix. Such affections occur throughout the entire span of woman's life.

Complications of the obstructed cervix are encountered in practice from adolescence to senility. Some obstructions are congenital in origin but the majority are acquired during postnatal life. Trauma, infection, neoplasms, radiation therapy, and senile atrophy are the leading etiologic factors. Despite their frequency and the gravity of many of their sequelae, obstructions of the cervix, except for the excellent contributions of Curtis, have received but scant attention in the literature. It may be timely, therefore, to review the general problem. Congenital malformations, pathological complications, prevention and treatment are surveyed.

EMBRYOLOGICAL CONSIDERATIONS

Clinical experience would indicate that perhaps less than 10 per cent of obstructed cervixes are congenital in origin. Developmental stenosis of the cervix may result from incomplete canalization of the distal extremities of the fused müllerian ducts. The obstruction in such cases may be situated at the external os ('pin-point os') anywhere along the cervical canal or at the level of the internal os. Curtis (8) has described the longitudinal ridges which traverse the length of the anterior and posterior cervical walls. From these elevations extend obliquely directed rugae, the *plicae palmatae*. The thickness of these ridges varies in different subjects and it is known that hyperplasia sometimes occurs to such an extent that actual obstruction, particularly at the time of premenstrual congestion, takes place. Curtis cautions that without anesthesia at times it may be almost impossible to dis-

tinguish the resistance of the normal oblique folds from the resistance offered by the pathologically obstructed cervix. The obliquely directed rugae have the tendency to 'catch' the uterine sound. Certain cervixes may be stenotic at the external os only, the canal proper and internal os being patent. Stenoses at the internal os may be either apparent or real. In small anteфлекed uteri it is often difficult to pass the standard uterine sound, whereas the No. 1 or No. 2 Hegar sound may be introduced with ease, especially if gentle traction is exerted by means of a tenaculum on the cervix which tends to rectify the abnormal flexion in such uteri. In the study of a suspected stenosis, another useful technique is to bend the tip of the uterine sound at a much shorter and sharper angle, when it may be that the internal os may be passed without difficulty, whereas otherwise the tip of the sound may possibly impinge upon the posterior wall of the cervix.

In evaluation it may be said that although congenital strictures of the cervix may occasionally occur, their significance and precise pathogenesis remain a provocative subject for embryological, anatomical and clinical investigation. Examination under anesthesia is sometimes necessary to establish the presence of a genuine obstruction of developmental origin. The notion that most instances of primary dysmenorrhea are based upon a congenital stenosis of the cervix is no longer tenable, although a small percentage of dysmenorrheic patients presenting a rigid, narrow cervix, particularly at the internal os, are benefited by dilatation of the cervix with or without the use of an intrauterine stem pessary (12, 27, 39).

ACQUIRED LESIONS

It is instructive to consider the wide variety of processes which have been found capable of producing an acquired stenosis or atresia of the cervix. A tabulation of the primary causes is presented in Table I.

1 *Infection* According to Ashton ulcerative changes in the vagina associated with diphtheria, scarlet fever and smallpox may close the external os. It is conceivable that intrauterine or neonatal infections of the lower genital tract may have the same effect. Gonococcal endocervicitis is a well known cause of cervical stricture. The lacerated and bruised puerperal cervix is fertile soil for bacterial invasion. Fibrous synechiae are readily converted into fibrous adhesions with subsequent stenosis. In certain instances of tuberculous endometritis enough specific granulation tissue may be elaborated in the region of the internal os so that uterine drainage is obstructed and pyometra results. Cervical strictures are frequently associated with instances of chronic endocervicitis of undetermined etiology. The deposition of fibrous tissue in the cervix is always a probability in any cervix which has been the seat of an acute or chronic recurrent infectious process regardless of the identity of the original infectious agent. Secondary bacterial invaders which are resident months or years after the original infection has been dealt with may have the ability to evoke more intense plastic reactive inflammation than has the primary infectious agent whether gonococcal streptococcal or otherwise. In his chapter on soft tissue dystocia, Schumann cites syphilis among the processes being capable of producing a dense undilatable stricture of the uterine cervix.

2 *Trauma* Practically any instrumentation of the cervix may so traumatize the epithelium that cicatrization with resulting stenosis ensues. Sounding of the uterine cavity which used to be a common office procedure may lead to abrasion of the mucosa, scar tissue and eventual stenosis. Dilatation and curettage if done too thoroughly can be traumatic, too vigorous curettage of the uterine cavity can lead to more or less complete ablation of functioning endometrium with subsequent permanent amenorrhea as well as to removal of too much endocervical mucosa. Cauterization of the cervix especially carbonization of the canal for endocervicitis stands at the top of the etiologic list as the most frequent cause of cervical stenosis of traumatic origin. Kleegman warns of the hazard of cer-

vical strictures and stenoses that attends electrosurgical methods of treating cervicitis. In the year 1906 Hunner recommended the Paquin cautery in the treatment of chronic endocervicitis. In the year 1911 Dickinson used the fine wire nasal tip instrument for the treatment of cervicitis.

Shaw reports a fatal case of peritonitis resulting from cauterization of the cervix at the time of supracervical hysterectomy. Autopsy traced the peritonitis to a postcauterization stump abscess. His comment is that the patient might have been saved by more thorough dilatation of the cervical canal after cautery.

Amputation of the cervix, trachelorrhaphy and tracheloplasty have all been followed by stricture or stenosis of the remaining cervix. Block reports an incidence of cervical stricture in 9 per cent of the patients subjected to conization of the cervix. Hendriksen in his report on 6550 cervical stumps calls attention to the occurrence of stricture in the 'frozen' stump with occasional abscess formation in the cervical wall and cervical pyometra. The topical application of necrotizing chemicals such as strong silver nitrate, chromic acid and other corrosive substances to

Fig. 1. The external os is the commonest site for stricture or atresia. This is the usual location for stenosis subsequent to cauterization of the cervix.

the cervical canal can evoke such tissue destruction that cicatrization and stenosis result. Frank relates how a forgotten piece of cervical gauze retained *in situ* for 2 years resulted in traumatic stenosis and hematometra. The perennial wearing of stem pessaries whether for therapeutic or contraceptive purposes may be followed by the same train of events. Israel and Harrel report 3 cases of severe pelvic inflammation which resulted from the employment of intracervical wish-bone pessaries used to achieve prolonged contraception. The indications and contraindications for stem pessaries have been thoroughly taken up by Weir, Douglass and Melody.

Vaginal delivery spontaneous or operative abortion spontaneous or induced vaginal hysterectomy Diehrsen's incisions of the cervix and the repair of fresh puerperal lacerations of the cervix, all have been followed by stenosis and stricture in certain instances. Bernstein and Walter found that injury sustained during delivery followed by infection was the most common cause of cervical stenosis in a group of 8 patients who developed hematometra; such etiology accounted for 3 of their cases. Inept forceps rotations, with shearing of the endocervical mucosa lay bare the field for the deposition of dense scar tissue and eventual stricture. Previous anterior vaginal hysterotomy has been seen to result in such a stenotic cervix that the next pregnancy required termination by cesarean section (30).

3 Radiation therapy The fibroplasia and cicatrization subsequent to radiation therapy whether radium or x ray is a well known cause of cervical stricture and stenosis. Arneson warns how the fibroplasia following x ray therapy for cervical carcinoma may make virtually impossible the insertion of intrauterine radium at a later date. In the year 1929 Bland made an interesting report upon the occurrence of pyometra following radium therapy for uterine cancer. He regarded pyometra as analogous to pyonephrosis in the kidney where the dominant character is not the supuration but the retention with distention of the organ. Carter analyzed 39 cases of pyometra from a bacteriological critique. He found that sterile pyometra occurred most frequently in uteri with carcinoma both before and after treatment, whereas no case of pyometra which occurred spontaneously that is without previous operation or radiation therapy was sterile. An interesting case of post-radiation cicatrix of the cervix with stenosis of the cervical canal and hematometra, occurring in a 35 year old secundipara who had previously received intrauterine radium for dysfunctional bleeding and subsequently estrogens to allay vasomotor symptoms of the menopause has recently been reported (26). Estrogens activated the endometrium with resulting menstruation which was retained and gradually distended the uterus drainage from which was obstructed because of postradiation cicatrix of the cervix. When the uterus was opened following hysterectomy the cervical canal was found to be completely obliterated and the uterine cavity was full of blood some fresh and some obviously old.

4. Neoplasms Carcinoma of the uterine cervix especially the endophytic variety is a frequent cause of cervical obstruction with resulting pyometra. Corporal carcinoma, if situated near the isthmus may cause blockage of uterine drainage, with attendant pyometra. A cervical myoma which grows into the canal can so obstruct menstrual drainage that acquired dysmenorrhea and hematometra may result. A relatively small myoma situated in the lower uterine segment or cervix may so effectively block the birth canal that abdominal delivery is necessary. An impacted inter-

Fig 2 Dense scar tissue is present at internal os and in the cervical canal. Such cicatrization has been encountered months or years after the use of intraterine radium therapy

Fig 3 Submucous myoma baling into the uterine cavity the caudal half of which is almost obliterated. Obstructed uterine drainage results from the ball valve action of such a myoma

Initial myoma of the posterior cervical wall may be an absolute obstruction to vaginal delivery. A pedunculated submucous myoma by protruding through the cervical canal in a ball valve fashion, may give rise to severe reflex uterine contractions and effectively obstruct uterine drainage, until it has been delivered through the cervix. Carter quotes a report by Reeb in 1928, in which the latter recounts the case of a 77 year old woman with a calcified concretion, so called 'womb-stone,' blocking the cervix with the production of pyometra, the patient had undergone dilation and curettage and radium application at the age of 44 for a small myoma. According to Scanzoni (32) obstructed uterine drainage may result from the extrinsic pressure of an ovarian cyst or neoplasm.

5 *Senile contracture* Senile atresia or contracture of the cervix is a natural part of the process of postmenopausal involution of the genitalia. The cervix becomes smaller and more conical in appearance. If secretions from the endometrium accumulate and are trapped behind the cervix bacteria invading by way of the cervix produce endometritis and eventual pyometra. This train of events may occur spontaneously in a cervix which has not been the seat of previous operation or malignancy. The syndrome of intermittent cervical obstruction in postmenopausal women

in which secretions accumulate giving rise to backache and lower abdominal distress only to be promptly relieved by the rather sudden escape of watery blood tinged leucorrhea has been described by Faulkner. The indiscriminate use of estrogens in postmenopausal women who have a closed cervix often eventuates in activation of the endometrium with resulting bleeding and trapping of the blood in the uterine cavity (hematometra). What with the ever growing number of postmenopausal women and particularly those who have had previous trauma infection or surgery upon the cervix the production of hematometra from the injudicious use of estrogens is becoming more and more common.

SYMPTOMATOLOGY

A galaxy of syndromes may result from an obstructed uterine cervix depending upon several variables namely (1) the location of the obstruction (2) the degree of the obstruction that is whether complete (atresia) or incomplete (stenosis) (3) the manner in which the obstruction occurs that is whether congenital or acquired, (4) the period of the woman's life when the obstruction manifests itself that is the menarche the childbearing, or the postmenopausal era and (5) the nature of the trapped secretions that is inflammatory products or blood.

Fig. 4. Pedunculated fibroid polyp approaching internal os. Gradual growth of polyp results in its extrusion through the cervical canal.

1 Cryptomenorrhea. Obstructed uterine drainage may be manifested by delayed menarche. The patient often presents herself with a chief complaint of primary amenorrhea. Careful anamnesis however may reveal that the individual has had cyclic moulina, with out, however any external bleeding. The commonest site of obstruction in such instances is the external os. The retention of menstrual blood over a period of months or years may gradually distend the uterus so that it becomes a soft symmetrically enlarged viscus the size of a gravid uterus of 3 or 4 months. The cervix may become converted into a smooth soft mass at the apex of the vagina, the cervical canal having become ballooned out by the hematometra process. The external os may be hardly visible and then only as a pigmented puckered point in the apex of the vaginal vault.

2 Dysmenorrhea. Curtis (9) states that the pain of obstructed uterine drainage varies from ill-defined discomfort to severe cramps. It used to be widely held that the hypoplastic acutely anteфлекed uterus, so often associated with primary dysmenorrhea, presented an actual obstruction at the internal os. However many patients with such uteri complain of cramps hours or even days before there is the slightest suspicion of flow hence the pathogenesis of pain in such cases is apparently based on some mechanism other than stenosis

of the cervix. Very probably it is associated with hyperemic distention of the viscera. Wear (40) has found that bending the tip of the uterine sound at a much shorter and sharper angle will often permit it to pass the internal os when otherwise the sound would obstruct against the posterior cervical wall at the level of the internal os. Traction on the cervix by straightening the acute angle at the internal os, often helps in achieving passage. Nevertheless in a rather small percentage of patients with a diminutive anteфлекed uterus it will be found that the internal os is so narrow and rigid that even the small surgical sound can only be passed with the greatest difficulty. In such instances clots may form in the uterine cavity and require forceful cramps to expel them. Such a narrow rigid internal os is almost certainly of congenital origin and the dysmenorrhea might properly be called obstructive.

An interstitial myoma in the cervix may gradually block the canal and give rise to severe acquired dysmenorrhea, from the reflex uterine contractions evoked in overcoming the obstruction. A pedunculated submucous myoma may give rise to continual uterine colic, until the tumor has been delivered through the external os.

3 Menorrhagia. Prolongation of the menses is frequently the presenting symptom in women of the childbearing age who have cervical obstructions. The period may last from 5 to 10 days and the bloody discharge may be intermittent during the bleeding episode. Not infrequently the actual bleeding phase passes over into an interval during which there is a more or less persistent discharge of tarry material which may last practically until the onset of the next menses.

4 Leucorrhoea. This is perhaps the commonest complaint caused by cervical stenosis in women in the reproductive and postmenopausal eras. Assuming that the usual infective incitants have been excluded, persistent or recurrent leucorrhoea in women of the childbearing age will often be found to be associated with an obstructed cervix. As pointed out by Henriksen leucorrhoea, odorless or malodorous, is a not uncommon complication of supracervical hysterectomy and results from the de-

development of stricture in the remaining cervix. The obstruction is usually found at the external os and, according to Henniksen, investigation will often disclose abscesses in the cervical wall or frank cervical pyometra. The tendency of the cervical stump to develop strictures has been attributed to impaired blood supply following ablation of the corpus uteri and to the cessation of the cyclic menstrual discharge through the cervical canal. The sudden onset of profuse leucorrhea in a postmenopausal woman requires that gynecologic investigation exclude the presence of a cervical stricture. Gradual closure of the cervix is a natural concomitant of the genital atrophy seen in senile involution. Faulkner describes the syndrome of intermittent cervical obstruction in postmenopausal women, characterized by low backache, vague lower abdominal pain and the sudden issue of a watery pinkish vaginal discharge. Dilatation and curettage done to exclude uterine malignancy reveals a stenotic cervix. The patient may remain asymptomatic for months or years, until secretions trapped behind the blocked cervix develop sufficient pressure to break through the obstruction thus repeating the syndrome of intermittent cervical obstruction. The alternate retention and drainage of trapped uterine secretions after menopause has been known to go on for years. If bacteria invade the uterine cavity through the stenotic cervix, endometritis followed by pyometra ensues.

5 Senile vaginitis. If there is little or no response to the usual medical treatment for atrophic vaginitis, the possibility of cervical stricture should be investigated. Cicatricial changes in the postmenopausal cervix are frequent to block the lumen of the cervix are frequent. Bacterial invasion of the trapped secretions may produce copious inflammatory products which gradually build up pressure head and seep through the cervix. The thin senile vaginal mucosa with its low glycogen content is readily irritated by such exudates. Without first establishing adequate surgical drainage of the retained inflammatory products, acidic vaginal douches and estrogens which in the uncomplicated case of senile vaginitis are usually so salutary, are quite ineffectual.

Fig. 5. Carcinoma of the cervix is one of the most common causes of pyometra.

6 Postmenopausal bleeding. In his analysis of 179 cases of postmenopausal bleeding TeLande found 6 cases (3.4%) to be due to chronic endometritis. In 5 of the 6 cases pyometra was found at operation. In the sixth case no mention was made of it in the operative note. The cause of the pyometra in the 5 cases was a benign stenosis of the cervical canal associated with senile contracture of the cervix. The typical presenting complaint in these patients was a blood tinged purulent discharge. Microscopic examination of the endometrium showed typical senile changes with the usual evidence of chronic inflammation. Pratt includes stenosis of the cervix among the many conditions which must be included in the differential diagnosis of bleeding associated with the menopause.

7 Infertility. Hamblen encountered cervical factors in 32 per cent of childless wives. Endocervicitis occurred in 22 per cent, poor drainage in 6 per cent and failure to receive spermatozoa in 4 per cent. Pin point external os, or strictures of the canal, impede physiological drainage and lead to inspissation of the mucous plug, with resulting physical and chemical alterations in the cervical mucus which eventuate in impenetrability or chemical hostility to spermatozoa. Impaired drainage often leads to infection and *vice versa*. The finding of thick, opalescent pus in the external os during the mid-cycle, when the cervical secretion should normally be thin transparent

Fig. 4. Pedunculated fibroid polyp approaching internal os. Gradual growth of polyp results in its extrusion through the cervical canal.

1 Cryptomenorrhea Obstructed uterine drainage may be manifested by delayed menses. The patient often presents herself with a chief complaint of primary amenorrhea. Careful anamnesis however may reveal that the individual has had cyclic moulina with out however any external bleeding. The commonest site of obstruction in such instances is the external os. The retention of menstrual blood over a period of months or years may gradually distend the uterus so that it becomes a soft, symmetrically enlarged viscus the size of a gravid uterus of 3 or 4 months. The cervix may become converted into a smooth soft mass at the apex of the vagina the cervical canal having become ballooned out by the hematometra process. The external os may be hardly visible and then only as a pigmented puckered point in the apex of the vaginal vault.

2 Dysmenorrhea. Curtis (9) states that the pain of obstructed uterine drainage varies from ill-defined discomfort to severe cramps. It used to be widely held that the hypoplastic acutely ante flexed uterus so often associated with primary dysmenorrhea presented an actual obstruction at the internal os. However many patients with such uteri complain of cramps hours or even days before there is the slightest suspicion of flow hence the pathogenesis of pain in such cases is apparently based on some mechanism other than stenosis

of the cervix. Very probably it is associated with hyperemic distention of the viscera. Weir (40) has found that bending the tip of the uterine sound at a much shorter and sharper angle will often permit it to pass the internal os when otherwise the sound would obstruct against the posterior cervical wall at the level of the internal os. Traction on the cervix by straightening the acute angle at the internal os often helps in achieving passage. Nevertheless, in a rather small percentage of patients with a diminutive ante flexed uterus it will be found that the internal os is so narrow and rigid that even the small surgical sound can only be passed with the greatest difficulty. In such instances clots may form in the uterine cavity and require forceful cramps to expel them. Such a narrow rigid internal os is almost certainly of congenital origin and the dysmenorrhea might properly be called obstructive.

An interstitial myoma in the cervix may gradually block the canal and give rise to severe acquired dysmenorrhea from the reflex uterine contractions evoked in overcoming the obstruction. A pedunculated submucous myoma may give rise to continual uterine colic, until the tumor has been "delivered" through the external os.

3 Menorrhagia Prolongation of the menses is frequently the presenting symptom in women of the childbearing age who have cervical obstructions. The period may last from 5 to 10 days and the bloody discharge may be intermittent during the bleeding episode. Not infrequently the actual bleeding phase passes over into an interval during which there is a more or less persistent discharge of tarry material which may last practically until the onset of the next menses.

4 Leucorrhoea. This is perhaps the commonest complaint caused by cervical stenosis in women in the reproductive and postmenopausal eras. Assuming that the usual infective incitants have been excluded persistent or recurrent leucorrhoea in women of the childbearing age will often be found to be associated with an obstructed cervix. As pointed out by Henriksen leucorrhoea, odorless or malodorous, is a not uncommon complication of supracervical hysterectomy and results from the de-

11 *Endometriosis* The pathogenesis of endometriosis has not been established how ever it seems not unlikely that an occasional case at least may result from reflux menstruation according to Sampson's theory. In patients suspected of having pelvic endometriosis finding the uterus in normal upright position should invite investigation of the cervical canal as to patency. Curtis (8) has found that a not uncommon cause of obstructed drainage is hyperplasia of the longitudinal ridges of the cervix.

Fullerton (17) feels that reflux menstrual discharge is the etiologic factor in perhaps the majority of cases of endometriosis. He believes that a tight cervix can be the cause of reflux perturbed menstruation. Maintaining that at the time of dilatation of the cervix with the usual solid metal dilators the intra uterine pressure is increased by the piston like action of the dilators. Fullerton has suggested that the ordinary dilators be modified by boring a tubular lumen (1 mm. in diameter) longitudinally through the center thus eliminating the piston action within the uterine cavity which he calls an anatomic syringe barrel.

12. *Conglutination of the external os* In this rather unusual obstetrical complication the presenting part is well engaged in the pelvis the cervix thin and effaced and tightly stretched over the presenting part but the os fails to dilate beyond a pin point opening the margins of which are rigid and sharp. This condition is more common in primiparas than in multiparas but has been known to recur in succeeding pregnancies (36). The stenotic external os usually very promptly opens in response to digital insinuation rarely. Dehrens' multiple incisions are required.

13. *Cervical dystocia* It is recognized that cervical dystocia may result from a galaxy of obstetrical conditions including neurogenic inhibition uterine inertia and cephalopelvic disproportion however previous surgical or other trauma to the cervix may evoke such cicatrization that the cervix will fail to efface and dilate during labor. Failure to recognize such a complication may result in rupture of the uterus (4). The correct treatment is cesarean section after a reasonable and closely

Fig. 6. Specimen removed from a 31 year old null gravida. Complaints included primary dysmenorrhea, sterility and menometrorrhagia. The small uterine probe could not be passed through the cervical canal. The cavity was greatly distended from hematometra and the uterine wall was one third normal in thickness. The rather large submucous myoma situated in the fundus uteri was an incidental finding. Note the dense scar tissue in the cervix and the lower uterine segment. The cause of the extensive cicatrization could not be ascertained. (Specimen courtesy of Dr. John A. Driscoll.)

supervised trial of labor. Certain instances of rupture of the uterus of rather obscure etiology may be traced to the sudden giving way of a badly scarred cervix with extension of the rupture into the broad ligament (18).

14. *Postpartum pyometra* Revcraft (31) has pointed out the importance of stenosis of the cervix with retention of lochia and pyometra as a cause of puerperal morbidity. The usual history is an operative vaginal delivery followed a week or two later by chills and fever, a tender distended uterus and scant or absent lochia. The same clinical picture may be seen following cesarean section especially when the section has been done for cervical dystocia after a test of labor. Recovery is usually quite prompt after the establishment of adequate surgical drainage by T-tube catheter introduced after gentle dilatation of the closed cervix.

TRI ATMENT

Historical notes Sir James Young Simpson (1811-1870) (33) quotes the Hippocratic writings (13th section) wherein the writer recommends that if the cervical orifice be very much contracted it be opened by means of bougies

and watery is evidence of a pathological endocervix. In instances of cervical hostility microscopic study of semen aspirated from the cervical canal will show absence of motile sperm.

The first clue to an obstructed cervix may be the inability to pass the Jarcho cannula at the time of the proposed Rubin's test for tubal patency. The frequency of pregnancies following nothing more than tubal patency test, whether by gas or iodized oil, may well be due as much to the benefit of dilating the cervix in passing the cannula as to the actual perfusion of the testing medium through the uterotubal system.

8 Hematometra. This requires a complete obstruction of the lower genital tract and a functioning endometrium. Bernstein and Walter in reporting 19 instances of hematometra, encountered 8 cases that resulted from cervical stenosis, the other 11 instances were congenital in origin including imperforate hymen (10 cases) and bicornuate uterus (1 case). Trauma sustained during delivery followed by infection (3 cases) was found to be the most common cause of stenosis. The other etiologic factors were cauterization, surgical removal of a cervical myoma, dilatation and curettage, x-ray and radium therapy, senile cervical contracture, and obstruction resulting from uterine myomas. Amenorrhea, lower abdominal pain, and a symmetrically enlarged soft uterine tumor are the typical findings in hematometra as well as in pyometra. The formation of hematometra is much more spectacular and rapid in development in menstruating than in postmenopausal women. In menstruating women with cervical atresia the distended uterus may enlarge to the size of a 3 months gestation in the matter of several months. Complaints referable to the abdomen may extend from a vague sensation of uneasiness to severe colic like lower abdominal pain. Hematometra as a sequela to the obstructed cervix is being encountered more frequently nowadays as a result of the universal use of cervical cauterization, the frequent utilization of conization of the cervix, and the not infrequent employment of radiation therapy. The case records of the Massachusetts General Hospital have recently included 3

most interesting instances of hematometra, resulting from the administration of estrogens to relieve menopausal symptoms in women with obstructed cervixes. The first patient (23) was a 54 year old woman who developed cervical stenosis as a result of conization of the cervix 4 months previously. The second instance (26) was a 35 year old secundipara whose cervical obstruction resulted from the administration of radiation therapy (radium) 8 months previously for the control of dysfunctional uterine bleeding. A common complication of estrogenic therapy is the so called withdrawal bleeding, a frequent sequela of operative procedures to the cervix is stenosis or atresia, resulting from cicatrization.

9 Hematosalpinx. Retained blood may proceed reflux to distend the fallopian tubes (hematosalpinx). If the fimbriated end of the tube is closed pyohematosalpinx may develop. The clinical picture of pyohematosalpinx is indistinguishable from acute salpingitis. If the fallopian tubes are open blood forced into the tubes from the uterus may escape into the peritoneal cavity and there produce varying amounts of hemoperitoneum. Although tubal pregnancy is the most common cause of hematosalpinx it is well to remember that the latter may be a complication of gynatrauma. The fimbriated end of the tube may close as a result of infection, as in salpingitis, or of aseptic inflammation as in tubal pregnancy.

10 Pyometra. The distention of the uterine cavity with inflammatory products gives rise to much the same symptomatology as is encountered in hematometra. In addition to the lower abdominal discomfort, there may be chills and fever and other evidence of sepsis. The serosanguineous material associated with the pus is thought to be the result of bleeding from the granulation tissue lining the pyogenic membrane into which the uterine cavity is converted. Occasionally the pyometra may result in such a rapid enlargement of the uterus in a postmenopausal woman that cellular myoma or sarcoma may be misdiagnosed and lead to needless hysterectomy (14). An unsuspected pyometra may be revealed in the routine investigation of abnormal uterine bleeding resulting from carcinoma of the cervix, an extremely common cause of pyometra.

As recommended by Weir and Melody a vaginal pessary of the Smith or the Hodge type should be worn concomitantly with the stem to prevent expulsion of the latter. Potter recommends a winged stem pessary to correct stenosis of the external os in certain selected cases of involuntary sterility. He reports having used such a device in 12 patients, in 8 of whom pregnancy subsequently occurred. In Potter's series sterility investigation was entirely negative except for stenotic cervix with associated cervical hostility as demonstrated by the Huhner postcoital test.

3 *Dilatation and evacuation* This is the procedure of choice in instances of pyometra and hematometra. Adequate surgical drainage of the trapped uterine contents may be insured by inserting a rubber T tube catheter such as is used in draining the common bile duct; the catheter should remain until drainage has been complete, which may be a matter of several days to several weeks. This is the ideal procedure for puerperal pyometra. Bacteriological cultures should be taken and processed anaerobically and aerobically.

4 *Anterior lip bisection* Very rarely if the obstruction cannot be opened by divulsion (Atlee and Goodell dilators) or by dilatation (surgical probes and small Hegar dilators) it may become necessary to advance the bladder and to make a small incision in order to find the strictured canal. This approach has been advocated by Curtis (10). Patency may be maintained by means of an intrauterine stem pessary or small rubber T tube catheter; the choice depending upon the presence or absence of infection and trapped secretions.

5 *Vaginal myomectomy* Certain obstructing cervical myomas can best be enucleated by the vaginal approach after advancing the bladder. Pedunculated submucous myomas are best removed by snare or by ligation and division of the pedicle if the latter be accessible; otherwise morcellation may be the procedure of choice. Caution must be taken in dividing the pedicle lest the fundus uteri may be cut across inasmuch as the fundus in such cases is sometimes inverted by the traction exerted by the pedunculated tumor. Transperitoneal removal of a pedunculated submucous myoma at the time of abdominal

Fig. 9. Instruments for opening strictured cervix. On the left is the Atlee cervical dilator. In the center are Hegar dilators, sizes 1, 2, 3, 4, 5, 6 French. These smaller sizes are usually not included in the routine setup for dilatation and curettage. On the right are intrauterine silver stem pessaries which may be used in selected cases for maintaining patency.

hysterectomy is mentioned to be condemned because of the grave risk of peritonitis from contaminating the peritoneal cavity.

6 *Hysterectomy* Vaginal or abdominal hysterectomy may be the procedure of choice in certain instances of symptomatic stricture of the cervix, particularly in women over the age of forty. This may be especially indicated if there are such complaints as increasingly severe dysmenorrhea and persistent vaginal discharge, and if the uterus is enlarged and tender to palpation. Greenhill prefers vaginal hysterectomy in such cases.

7 *Radiation* When uterine cancer is associated with pyometra from impaired uterine drainage, intrauterine radium is to be avoided until all evidence of infection has disappeared, if metritis, pelvic cellulitis, and peritonitis are to be averted. Preliminary x-ray in order after surgical drainage has been established, the sterilizing effect of roentgen rays in such situations is most striking.

8 *Cesarean section* The rationale of timely abdominal delivery in genuine cervical dystocia is obvious if obstructed labor and its complications are to be avoided. It is pending upon the character of the obstruction whether penicillin or streptomycin

Fig. 7. Photomicrograph showing chronic endometritis, associated with pyometra in postmenopausal woman. The benign contracture of the cervix. Uterus globular shaped, rapidly grew to size 14 months pregnancy. Hysterectomy was done because of suspicion of malignant myoma. There is extensive, diffuse infiltration of the endometrium by lymphocytes and plasma cells. Note the large foreign body giant cells frequently encountered in any pyogenic menbrane (Specimen courtesy Dr. Robert L. Faulkner)

Fig. 8. Photomicrograph of transsection through normal uterine tube at time of menstruation. Note islands of menstruating endometrium free in tubal lumen. Reflex menstruation may be of biologic importance in some instance of endometriosis. Cervical obstruction, uterine retrodisplacement, and increasing intra-uterine pressure by the use of solid cervical dilators may be factors in promoting retrograde menstruation. (Specimen, courtesy of Dr. Robert L. Faulkner)

and leaden instruments. Simpson also refers to a textbook entitled *Afarro of Chirurgery* by one Mr Cook a practitioner of Warwick, in which the author in speaking of closure of the inner orifice of the womb or os uteri recommends it to be enlarged when necessary by gentian root or prepared sponge and afterwards by the introduction of hollow instruments of silver ivory or horn and these means, he adds are better than incision. Simpson himself advocates surgical division of the cervix along its entire length with an instrument he called the hysterotome or metrotome. Scanzoni (32) describes his method of evacuating retained menstrual blood in cases of hematometra by means of introducing a trochar into the most depending and accessible point of the tumor which the lower portion of the womb forms in the vagina. He reports having treated 3 such cases of congenital obstruction at the external os with associated hematometra by the aforementioned approach without a fatality and without complications.

1. *Dilatation of the cervix* Opening of the obstructed cervix by means of dilating instruments is the most commonly done surgical procedure in the management of stricture.

When difficulty is encountered in introducing graduated dilators, such as those of the Hegar type much can often be accomplished by employing a spreading or divulsing instrument, such as the Atlee dilator. The latter will often be successful in reopening the natural passageway when a tubular dilator will make no advance whatsoever. If graduated dilators are used it is essential to have available the smallest ones, including the Hegar No. 1 and No. 2 which are usually not included in the ordinary set up for dilatation and curettage. Web-like curtains at the external os can often be opened with the smaller surgical probes if only the puckered point indicating the obliterated external os can be identified. Caution and gentleness should be the watchword in approaching these cases particularly if there be an associated pyometra or hematometra.

2. *Dilatation of the cervix and stem pessary* In the occasional stricture without any associated infection including cervicitis and adenitis the intrauterine silver stem of the Chambers type may be used to advantage after the obstruction has been overcome. The stem may be left in place for 3 to 6 months, to insure maintenance of established patency.

As recommended by Weir and Melody a vaginal pessary of the Smith or the Hodge type should be worn concomitantly with the stem to prevent expulsion of the latter. Potter recommends a winged stem pessary to correct stenosis of the external os in certain selected cases of involuntary sterility. He reports having used such a device in 12 patients in 8 of whom pregnancy subsequently occurred. In Potter's series sterility investigation was entirely negative except for stenotic cervix with associated cervical hostility as demonstrated by the Huhner postcoital test.

3 *Dilatation and evacuation* This is the procedure of choice in instances of pyometra and hematometra. Adequate surgical drainage of the trapped uterine contents may be insured by inserting a rubber T tube catheter, such as is used in draining the common bile duct. The catheter should remain until drainage has been complete, which may be a matter of several days to several weeks. This is the ideal procedure for puerperal pyometra. Bacteriological cultures should be taken and processed anaerobically and aerobically.

4 *Anterior lip bisection* Very rarely if the obstruction cannot be opened by divulsion (Atlee and Goodell dilators) or by dilatation (surgical probes and small Hegar dilators) it may become necessary to advance the bladder and to make a small incision in order to find the structured canal. This approach has been advocated by Curtis (10). Patency may be maintained by means of an intrauterine stem pessary or small rubber T tube catheter. The choice depending upon the presence or absence of infection and trapped secretions.

5 *Vaginal myomectomy* Certain obstructing cervical myomas can best be enucleated by the vaginal approach, after advancing the bladder. Pedunculated submucous myomas are best removed by snare or by ligation and division of the pedicle if the latter be accessible otherwise morcellation may be the procedure of choice. Caution must be taken in dividing the pedicle lest the fundus uteri may be cut across inasmuch as the fundus in such cases is sometimes inverted by the traction exerted by the pedunculated tumor. The transperitoneal removal of a pedunculated submucous myoma at the time of abdominal

hysterectomy is mentioned to be condemned because of the grave risk of peritonitis from contaminating the peritoneal cavity.

6 *Hysterectomy* Vaginal or abdominal hysterectomy may be the procedure of choice in certain instances of symptomatic stricture of the cervix particularly in women over the age of forty. This may be especially indicated if there are such complaints as increasingly severe dysmenorrhea and persistent vaginal discharge and if the uterus is enlarged and tender to palpation. Greenhill prefers vaginal hysterectomy in such cases.

7 *Radiation* When uterine cancer is associated with pyometra from impaired uterine drainage, intrauterine radium is to be avoided until all evidence of infection has disappeared. If metritis, pelvic cellulitis and peritonitis are to be averted. Preliminary x ray is in order after surgical drainage has been established. The sterilizing effect of roentgen rays in such situations is most striking.

8 *Cesarean section* The rationale of timely abdominal delivery in genuine cervical dystocia is obvious if obstructed labor and possible uterine rupture are to be avoided.

9 *Antibiotics* Depending upon the bacteriological findings either penicillin or strepto-

mycin may be indicated in the prophylaxis of complications after evacuating a hematometra or pyometra. Antibiotics are to be regarded as an adjunct not a substitute for surgical drainage.

PREVENTION

The guiding principle with regard to the therapeutics of the cervix uteri should be *primum non nocere*. Accouchement forcé and delivery through the incompletely dilated cervix have no place in modern obstetric practice. It is noteworthy that in a recent analysis of 77 cases of failed forceps in patients admitted to three Dublin hospitals for treatment the cervix was not fully dilated in half of the patients (15). Great care and due gentleness must be observed whenever forceps rotations are required lest damage to the cervix with subsequent cicatrization be sustained. Fresh cervical lacerations and Dehriesen's incisions must be repaired meticulously. Patients who have been subjected to such operative procedures should not be discharged 6 weeks post partum; instead they should be rechecked 3 or 6 months later for possible cervical stricture or atresia.

The widespread use of cauterization, conization, cervical repair and amputation, intra-uterine radium and pelvic irradiation have taken their toll in cicatrized cervixes. It is recognized that the persistent administration of estrogens for the menopausal syndrome not infrequently activates a dormant endometrium into bleeding. If the cervix is closed, hematometra may follow; this train of events is becoming more and more frequently observed. In passing it might be stated that the use of estrogens in not a few instances has been indeed casual. Patients who have been subjected to operative procedures on the cervix including supracervical hysterectomy or radiation therapy should be followed at regular intervals on which visits the cervix should be inspected, palpated and sounded (with all due aseptic precautions) to ascertain and maintain patency of the canal. The Atlee cervical dilator is ideal for this purpose although the smaller Hegar instruments may be quite satisfactory. If a high-grade stenosis is encountered, dilatation may have to be carried out under anesthesia. Cauterization and coni-

zation demand periodic follow up observations for at least 6 months.

SUMMARY

The general subject of the obstructed uterine cervix has been reviewed. The natural history of cervical obstructions, as well as the clinical syndromes associated therewith has been considered. A plea has been made for the avoidance of trauma to the cervix both in obstetric and gynecologic practice. A critique of the various methods available in the management of the obstructed cervix has been presented. It has been emphasized that obstructive lesions of the uterine cervix are far from a rarity in everyday practice and will be encountered with increasing frequency as the clinician becomes mindful of their possibility in his evaluation of obstetrical and gynecological problems.

THE TECHNIQUE OF SURGICAL DIVISION OF PATENT DUCTUS ARTERIOSUS

OWEN H. WANGENSTEEN M.D. F.A.C.S. RICHARD L. VARCO M.D., and
IVAN D. BARONOFSKY M.D., Minneapolis, Minnesota

WHEN Robert Gross (6) successfully interrupted the continuity of the ductus arteriosus he released an attack renewed in many surgical clinics upon crippling congenital vascular lesions which has brought laurels to surgery and help to patients whose condition heretofore was believed unremediable. Anomalies of embryological development which aroused only occasionally the curiosity of students of pathology now have become the absorbing interest of many surgical clinics as well as the subject of everyday table-talk and newspaper comment. Such is the power of a ferment. Blalock's (1) bold and well conceived rehabilitation of the cyanotic child with pulmonic stenosis from invalidism to limited activity has caught the public imagination as few things in medicine ever have. And Crawford's courageous excision of the strictured area in coarctation of the aorta has won the admiration of all physicians.¹ These technical accomplishments of surgeons have lent exciting interest to the correction of crippling congenital vascular anomalies—and hope to many born to bear the tragic burden of an imperfection in a vital area.

When the history of surgery of this era is written the importance of the stimulus to vascular surgery of Gross's successful interruption of the patent ductus will be generally appreciated. Gross has told the story of previous unsuccessful attempts at ligation of the ductus

and how he worked out the details of the operative approach upon the dog. It perhaps is not without interest to relate here that Dr. George E. Fahr, Professor of Medicine suggested to one of us in 1935 that he considered ligation of the patent ductus a feasible and desirable surgical venture. When the late Elliott Cutler came out from Boston in February, 1935 to give the E. Starr Judd Lecture in surgery at the University of Minnesota Medical School, Doctor Fahr showed us a 2-year-old patient with a large heart and signs of impending cardiac failure from a patent ductus. Cutler, an experienced investigator in cardiac surgery, suggested that a Parham band be placed around the ductus if the operation was undertaken. Probably fortunately for the patient she declined an operation which had not yet then been performed. The first patient selected by Gross for the operation was a child of 7 years. All who have had an experience with the procedure of ligation or division of the ductus can well understand the difference in the surgical problem posed by a child of 7 and a large woman of 22 years with a large heart.

LIGATION OR DIVISION?

Dissatisfaction with simple ligation of the ductus owing to the circumstance that recanalization occurred now and then persuaded Gross (7) to divide the ductus. This suggestion has been taken up in this clinic too and for the same reason. Dr. M. J. Shapiro who stimulated local interest in this problem following the initial report of Gross and who was responsible for the selection of all the patients for operation in the early stages of the effort here estimates that recanalization occurs in approximately 10 per cent of patients after ligation. Our own experience in this clinic during the period when ligation was done (September, 1939 to November, 1941) is in accord

¹From the Department of Surgery, University of Minnesota, Minneapolis, Minnesota.

This work was supported by the Scarle Fund for Surgical Research and grant from the Graduate School of the University of Minnesota.

²Publications on the surgery of coarctation of the aorta by Gross and Crawford appeared almost simultaneously. The paper of Gross and Huber, appeared in the *New England Journal of Medicine* for September 6, 1943, volume 233, page 257; that of Crawford and N. I. in *October Journal of Thoracic Surgery* 1943, volume 37, page 347. Gross' first patient was operated upon June 29, 1943 (Crawford) on October 19, 1944. Crawford's publication carries the following editorial footnote: Received for publication June 1, 1945.

Fig. 1. Surgical division of the ductus. 1 The exposure after division of the mediastinal pleura behind the phrenic nerve. The dissection of the fibrous pericardium overlying the anteromedial angle between pulmonary artery and aorta is commenced. 2 A curved hemostat is pushed through from the outer side of the ductus after a communication has been established between the inner and the outer dissection. The illuminated lucite dissector shown in Figure 3 is a helpful agent in indicating the direction of the dissection in the inner medial angle between pulmonary artery, ductus, and aorta as well as in the final stages of the dissection. The separation of the thick fibrous layer of the pericardium from the thin inner serous layer is shown in the insert between 1 and 2. 3 and 4. Application of hemostats after completion of the dissection. The long hemostat shown in Figure 3a facilitate the operative procedure. 5

The ductus is divided with a knife. Three or four hemostats or clamps may be applied if only three are employed a longer cuff is left on the aortic side as is shown in the diagram. Freeing the fibrous tissue from the adjacent vessel wall enlarges the working distance between ductus, pulmonary artery and aorta such that the hemostats may be placed more readily upon the ductus (see text). 6 The upper clamp has been removed and a running suture of fine silk (No. 0000 or No. 00000) is employed to oversew the cuff. A No. 000 silk suture is anchored in a remnant of the fibrous pericardium just beyond the site at which the clamp grips the vessel wall that site should be as near the vessel wall as possible certainly less than 3 millimeters from the grasp of the vessel wall in the clamp. The accurate placement and ligature of this suture insures complete hemostasis.

with such a suggestion. Among 16 patients in which simple ligation of the ductus was done recanalization occurred in 2 patients.

There is by no means however complete unanimity amongst surgeons that division is preferable to ligation. The discussion (9) following a recent paper by Gross (8) in 1947 indicates clearly that some surgeons dissent from the opinion that division of the ductus is

a better operation. Even so experienced and accomplished a thoracic vascular surgeon as Blalock (2) in 1946 appears to favor ligation over division of the ductus. The basis of this difference in attitudes is the circumstance that mere ligation is a simpler and safer operation than division otherwise everyone would agree that division is the safer operation from the standpoint of avoidance of recanalization

THE TECHNIQUE OF SURGICAL DIVISION OF PATENT DUCTUS ARTERIOSUS

OWEN H. WANGENSTEEN, M.D., F.A.C.S., RICHARD L. VARCO, M.D., and
IVAN D. BARONOFFSKY, M.D., Minneapolis, Minnesota

When Robert Gross (6) successfully interrupted the continuity of the ductus arteriosus he released an attack renewed in many surgical clinics upon crippling congenital vascular lesions which has brought laurels to surgery and help to patients whose condition heretofore was believed unremediable. Anomalies of embryological development which aroused only occasionally the curiosity of students of pathology now have become the absorbing interest of many surgical clinics as well as the subject of everyday table talk and newspaper comment. Such is the power of a ferment! Blalock's (1) bold and well conceived rehabilitation of the cyanotic child with pulmonic stenosis from invalidism to limited activity has caught the public imagination as few things in medicine ever have. And Crafoord's courageous excision of the strictured area in coarctation of the aorta has won the admiration of all physicians.¹ These technical accomplishments of surgeons have lent exciting interest to the correction of crippling congenital vascular anomalies—and hope to many born to bear the tragic burden of an imperfection in a vital area.

When the history of surgery of this era is written the importance of the stimulus to vascular surgery of Gross's successful interruption of the patent ductus will be generally appreciated. Gross has told the story of previous unsuccessful attempts at ligation of the ductus

and how he worked out the details of the operative approach upon the dog. It perhaps is not without interest to relate here that Dr. George E. Fahr, Professor of Medicine, suggested to one of us in 1935 that he considered ligation of the patent ductus a feasible and desirable surgical venture. When the late Elliott Cutler came out from Boston in February, 1935 to give the E. Starr Judd Lecture in surgery at the University of Minnesota Medical School, Doctor Fahr showed us a 2-year-old patient with a large heart and signs of impending cardiac failure from a patent ductus. Cutler, an experienced investigator in cardiac surgery, suggested that a Parham band be placed around the ductus if the operation was undertaken. Probably fortunately for the patient she declined an operation which had not yet then been performed. The first patient selected by Gross for the operation was a child of 7 years. All who have had an experience with the procedure of ligation or division of the ductus can well understand the difference in the surgical problem posed by a child of 7 and a large woman of 22 years with a large heart.

LIGATION OR DIVISION

Dissatisfaction with simple ligation of the ductus owing to the circumstance that recanalization occurred now and then persuaded Gross (7) to divide the ductus. This suggestion has been taken up in this clinic too and for the same reason. Dr. M. J. Shapiro, who stimulated local interest in this problem following the initial report of Gross and who was responsible for the selection of all the patients for operation in the early stages of the effort here, estimates that recanalization occurs in approximately 10 per cent of patients after ligation. Our own experience in this clinic during the period when ligation was done (September, 1939 to November, 1941) is in accord

Publications on the surgery of coarctation of the aorta by Crafoord and Gross appeared almost simultaneously. The paper of Gross and Harber appeared in the *New England Journal of Medicine* for September 6, 1943, volume 233, page 257; that of Crafoord and Gross in October *Journal of Thoracic Surgery* 1943, volume 37, page 347. Gross' first patient was operated upon June 28, 1943. Crafoord's on October 19, 1944. Crafoord's publication carries the following editorial footnote: Received for publication June 1, 1945.

discerned. Whereas, some separation is permissible by employment of a blunt curved hemostat it is our plan in the main to perform the entire dissection under direct vision using scissors and elevating tissues to be dissected off the wall of the ductus with hemostats. A curved, illuminated lucite elevator or dissector has been very helpful in identifying the plane through which the dissection should proceed. By grasping with a hemostat the areolar tissue (probably remnants of the serous layer of the pericardium) lying directly over the top of the illuminated lucite elevator an opening is made establishing a direct connection between the medial and the lateral portions of the dissection. One of us (O H W) who is partial to this maneuver in completing the dissection employs this technique routinely, frequently switching off all other operating room lights to facilitate identifying and dividing the areolar tissue, at the inner most posterior angle, tipped forward by the illuminated lucite dissector, which has been pushed beneath the ductus from its lateral aspect. Once penetration through the fibrous pericardium surrounding the ductus is achieved, enlargement of that orifice is readily accomplished by elevating and cutting the edges of the adjacent fibrous tissue.

Inasmuch as the wound is often deep long straight narrow hemostats of the Halsted or Rankin pattern have been made up to facilitate division of the ductus (Fig 3a). Four such clamps are placed care also is observed to avoid the recurrent laryngeal nerve with placement of the uppermost clamp on the aortic side and each clamp is pushed home to the last notch on the clamp. The ductus is cut with a knife between the two middle clamps. In the placement of the clamps it is important to have the tip of the clamp just grasp the inner wall of the ductus. Following division a No 000 silk suture is placed at the inner angle in the remnants of the fibrous pericardium immediately adjacent to the ductus wall at the level of the lower clamp before the upper one is removed. This suture is simply a safety device rarely needed but very convenient to permit elevation of the inner angle should there be any difficulty with subsequent steps in the operative technique. Such a suture is

placed on both the pulmonary artery side as well as the aortic side of the ductus before the upper clamp on each side is removed. The illuminated lucite dissector mentioned previously is an extremely useful instrument too in deciding that the lower clamp on each side actually has the entire vessel wall in its grasp. Should the surgeon have any misgivings on this score the placement of a mattress suture of fine silk (No 0000) at the inner angle between the upper and lower clamps before the latter is removed will eliminate any potential hazard ensuing from failure to place the lower clamp completely across the arterial wall. Strange as it may seem it is occasionally difficult to decide definitely exactly where the vessel wall ends and where the perivascular fibrous tissue begins. Following the example of Gross we place a running suture of fine silk (No 0000 or No 00000) over the remnant or cuff of tissue projecting above the lower clamp. However before removing the remaining clamp an additional stuck tie or horseshoe suture of No 000 silk is anchored with great care in the remnants of the fibrous pericardium immediately adjacent to the duct wall. As the remaining clamp is removed, this ligature is tightened and tied so that complete hemostasis is insured. The exact placement of this suture requires the greatest care for it is an important item in the safety of division and ligation of the ductus. In the manipulation of the clamps following division of the ductus every one touching a clamp is cautioned to hold it only by one shank or ring thus precluding any inadvertent releasing action occasioned by manipulation of both handles of the clamp.

RESULTS

Every patient whose patent ductus arteriosus has been interrupted by us since this series of operations began following Gross's publication on division of the ductus has had operative division of the ductus employing the principles of the technique described herein. On several occasions confronted with a wide but short and deeply located ductus in a large subject it has been difficult to resist the temptation of simply ligating the ductus. It is in just such cases however, in which the communication between the aorta and pulmonary

Fig. 2. The illuminated lucite dissector employed to indicate the direction of the dissection as well as the final establishment of communication between the inner and outer dissection. It is attached to a low voltage battery commonly employed for operating room cauteries. During the use the area in which the penetration is to be accomplished may be more readily observed by cutting off temporarily all other sources of illumination.

Certainly no one would approve of simple ligation of an arteriovenous communication in an extremity. The difficulties and hazards of reoperation for patent ductus are even more real than for a peripherally located arteriovenous fistula. Why not take maximal pains therefore to thwart the possibility of recurrence in the first operation?

SURGICAL DIVISION OF THE DUCTUS

In 1944 and again more recently in 1947 Gross (7-8) has outlined the plan of operation for division of the ductus. Since the publication of his first paper upon the technique we have followed his general plan of operation with minor variations. An anterior incision is employed usually obliquely across the anterior chest wall occasionally beneath the breast when it is well developed. The problem of the dissection is not a simple matter particularly in older patients in whom both the heart and the pulmonary artery may be large. Moreover the ductus itself as well as the walls of the adjacent pulmonary artery and aorta is not as tough as the fibrous layer of the pericardium from which it must be separated. This circumstance affords a real handicap in any dissection. And when the tissues to be separated are deeply situated and are conduits for blood the difficulties are apparent. As Gross has indicated when a lapet of pericardium covers the ductus anteriorly only it

Fig. 3. Other special instruments employed in the dissection. a, A long narrow straight hemostat. b, A long needle holder. c, A curved dissector. d, An ordinary curved clamp (Guyon Pean) for grasping the kidney pedicle is employed to complete the dissection shown in Figure 2.

may be dissected off. More often than not, however in our experience the medial wall of the ductus in the plane which must be developed in the dissection between the aorta and the pulmonary artery appears to be well supported by a reflection of the pericardium. Earlier in our experience and especially in adults with large hearts, when the dissection in the anteromedial angle between aorta and pulmonary artery seemed difficult we resorted to the expedient of deliberately opening the pericardial sac over the root of the pulmonary artery, separating the outer fibrous from the inner thinner serous layer of the pericardium. This separation facilitates the dissection. With increasing experience however the necessity for opening the pericardial sac to identify the outer fibrous layer of the pericardium has become very infrequent. Removal of the fibrous layer of the pericardium from the ductus without injury to its wall is essentially the problem posed by the operation. With the fibrous layer of the pericardium removed from the ductus progress in the dissection is readily

discerned. Whereas, some separation is permissible by employment of a blunt curved hemostat, it is our plan in the main to perform the entire dissection under direct vision using scissors and elevating tissues to be dissected off the wall of the ductus with hemostats. A curved, illuminated lucite elevator or dissector has been very helpful in identifying the plane through which the dissection should proceed. By grasping with a hemostat the areolar tissue (probably remnants of the serous layer of the pericardium) lying directly over the top of the illuminated lucite elevator, an opening is made establishing a direct connection between the medial and the lateral portions of the dissection. One of us (O H W) who is partial to this maneuver in completing the dissection, employs this technique routinely, frequently switching off all other operating room lights to facilitate identifying and dividing the areolar tissue, at the inner most posterior angle, tipped forward by the illuminated lucite dissector, which has been pushed beneath the ductus from its lateral aspect. Once penetration through the fibrous pericardium surrounding the ductus is achieved, enlargement of that orifice is readily accomplished by elevating and cutting the edges of the adjacent fibrous tissue.

Inasmuch as the wound is often deep long straight narrow hemostats of the Halsted or Rankin pattern have been made up to facilitate division of the ductus (Fig 3a). Four such clamps are placed, care also is observed to avoid the recurrent laryngeal nerve with placement of the uppermost clamp on the aortic side and each clamp is pushed home to the last notch on the clamp. The ductus is cut with a knife between the two middle clamps. In the placement of the clamps it is important to have the tip of the clamp just grasp the inner wall of the ductus. Following division a No. 000 silk suture is placed at the inner angle in the remnants of the fibrous pericardium immediately adjacent to the ductus wall at the level of the lower clamp before the upper one is removed. This suture is simply a safety device rarely needed but very convenient to permit elevation of the inner angle should there be any difficulty with subsequent steps in the operative technique. Such a suture is

placed on both the pulmonary artery side as well as the aortic side of the ductus before the upper clamp on each side is removed. The illuminated lucite dissector, mentioned previously, is an extremely useful instrument too in deciding that the lower clamp on each side actually has the entire vessel wall in its grasp. Should the surgeon have any misgivings on this score the placement of a mattress suture of fine silk (No. 0000) at the inner angle between the upper and lower clamps, before the latter is removed, will eliminate any potential hazard ensuing from failure to place the lower clamp completely across the arterial wall. Strange as it may seem, it is occasionally difficult to decide definitely exactly where the vessel wall ends and where the periarterial fibrous tissue begins. Following the example of Gross we place a running suture of fine silk (No. 0000 or No. 000000) over the remnant or cuff of tissue projecting above the lower clamp. However before removing the remaining clamp an additional stick tie or horseshoe suture of No. 000 silk is anchored with great care in the remnants of the fibrous pericardium immediately adjacent to the duct wall. As the remaining clamp is removed, this ligature is tightened and tied so that complete hemostasis is insured. The exact placement of this suture requires the greatest care for it is an important item in the safety of division and ligation of the ductus. In the manipulation of the clamps following division of the ductus every one touching a clamp is cautioned to hold it only by one shank or ring, thus precluding any inadvertent releasing action occasioned by manipulation of both handles of the clamp.

RESULTS

Every patient whose patent ductus arteriosus has been interrupted by us since this series of operations began following Gross's publication on division of the ductus has had operative division of the ductus employing the principles of the technique described herein. On several occasions confronted with a wide, but short and deeply located ductus in a large subject it has been difficult to resist the temptation of simply ligating the ductus. It is in just such cases however in which the communication between the aorta and pulmonary

artery is wide that division as contrasted with simple ligation offers the patient the best assurance against recanalization. In the easy case in which the ductus is long ligation may hold out almost as bright a prospect of permanence as division with respect to recanalization. But if division is necessary to protect against the possibility of rechanneling following ligation in continuity why merely ligate in the easy case? There have been 69 divisions of the ductus in this series with 1 death. Recanalization has not occurred.

COMPLICATIONS

Hemorrhage. In 1 instance in this series one of us (O.H.W.) fell afoul of the inherent difficulties of division. It concerned a large woman (Univ. Hosp. No. 780 697) of 31 years with subacute bacterial endocarditis, auricular fibrillation and cardiac decompression and a large patent ductus. She was a precarious operative risk and had been having chills and fever accompanied by dyspnea, anorexia, and weight loss of 6 months duration. There had also been episodes of pulmonary infarction with hemoptysis and chest pain. The auscultatory cardiac findings were typical of a patent ductus. On examination here multiple petechial hemorrhages were noted in the skin. The patient was cyanotic and dyspneic. The vital capacity was 0.9 liter, there was blood in the urine and the blood urea nitrogen was 90 milligrams per cent. Under penicillin therapy 3,000,000 units per day for 4 weeks the fever which had ranged between 100 and 101 degrees gradually subsided. The patient improved with digitoxin, a salt free diet and small frequent blood transfusions. The advisability of undertaking operation was debated and was undertaken as a last resort measure, no one feeling any real enthusiasm for the procedure. At operation a very broad ductus measuring more than 30 millimeters in width was found. The dissection about the ductus was tedious and difficult, occupying more than 2 hours. It was accomplished however without too much difficulty, the illuminated dissector proving a real help. The urge to terminate the operation by ligation was real. Mindful of the circumstance that it is in just such cases that the greatest hazard of recanalization lies, division

was done. The aortic side of the ductus was dealt with without difficulty. When the stick tie ligature behind the lower clamp on the pulmonary artery side was drawn up, however, the vessel tore, the bleeding was arrested by digital pressure without too much difficulty and a small hemostat was substituted for digital compression at the site of leak when however ligature of the bleeding point was attempted by placement of another mattress suture the pulmonic end of the ductus tore again. This procedure was repeated four times before hemostasis was complete. It had become quite obvious that a granulomatous process probably involved the vessel wall. Meanwhile the blood loss had been large but had been replaced adequately by blood run in through two intravenous infusion needles placed prior to operation. Fibrillation of the auricles set in followed by cardiac arrest. Ventricular contractions were restarted several times by cardiac massage and epinephrine but effective continued ventricular contractions could not be induced. At autopsy the heart weighed 715 grams. On the aortic side of the ductus in which no special difficulty had been encountered in the operation, 3 or 4 tiny friable vegetations measuring 1 millimeter in diameter were found. "In the pulmonary trunk there were several cracks in the intima and there was a large patch of vegetation on the anterior wall of the pulmonary trunk which extended to the left pulmonary artery where it surrounded the origin of the ductus."

The difficulty encountered at operation after division of the ductus is quite understandable in the light of the postmortem findings.

Trying difficulties with hemostasis occurred in only 1 other instance. It concerned a girl of 14 years with pallor in whom a suspicion of subacute bacterial endocarditis had been entertained but not established. She too had a broad short ductus, however the vessel wall held sutures better than the patient referred to previously and the situation though critical turned out happily.

Fever. In a young child of 5 years who had been febrile intermittently for months prior to operation, running a fever as high as 101 to 102 degrees Fahrenheit daily in the afternoon

fever continued intermittently for about a month after operation affording us serious concern lest a small cottonoid sponge had been lost in the wound. The fever eventually disappeared entirely. During convalescence too probably, this patient's fever was caused by subacute bacterial endocarditis which diagnosis had not been established definitely prior to operation.

Pleural fluid. Aspiration of pleural fluid has been necessary in approximately one third of the patients. Amongst the adults in the series accumulation of pleural fluid has been more frequent than in children. More than one aspiration has been unusual.

Temporary paralysis of arm. One patient in the group sustained a temporary paralysis of the muscles of the left hand and forearm supplied by the brachial plexus, undoubtedly owing to inadequate padding of the left axilla.

Cardiac arrest. One other patient for whom operation was undertaken for a patent ductus but not completed because of temporary cardiac arrest bears special mention. She was a beautiful child of 4 years (Univ Hosp No 775869). The chest had barely been opened when cardiac arrest occurred. Such grim and tense moments upset the quiet but serious atmosphere of an operation progressing satisfactorily. Differences of opinion and attitudes toward causation as well as mode of management are understandable in such trying conditions. Valuable time was lost in this instance through the insistence of the anesthetist that the vagus nerve should be injected with procaine first, that procaine should be injected into the pericardium and then into the ventricle. All these things were done, the heart muscle being massaged meanwhile, blood also being dripped into an ankle vein. The anesthetist's uneasiness relating to the use of epinephrine concerned his fear that inasmuch as cyclopropane anesthesia had been employed, ventricular fibrillation would be induced by epinephrine. One cubic centimeter of epinephrine was then injected into the left ventricle. Effective cardiac contractions began directly. A few minutes later an additional 0.5 cubic centimeter of 1:1000 dilution of epinephrine was given again. The second period was of only a few minutes duration.

The chest wall was closed without attempting dissection or exposure of the ductus. As the final skin sutures were placed cardiac arrest occurred again, oxygen only having been administered by inhalation meanwhile. The chest was opened again and the heart was massaged followed by reinjection of 0.5 cubic centimeter of epinephrine with immediate commencement of ventricular contractions. The anesthetist's record indicated that no blood pressure was obtainable for 45 minutes in the first long period of cardiac arrest.

The cause of the cardiac arrest in this patient has not been uniformly agreed upon. The consensus, however, is that it probably was owing to too high a concentration of carbon dioxide in the alveolar mixture. In other words, anesthetists are sorely in need of agents which will tell them more definitely and promptly from time to time in operations what the likely concentration of carbon dioxide is in the alveolar air.¹

The more remote occurrences in this patient are equally as interesting. For several days the patient was unconscious, responding only to painful stimuli for a period of almost a week. She also was oliguric, excreting only 15 to 60 cubic centimeters of urine a day with a low specific gravity. During this time she was weighed twice daily, enough 50 per cent glucose solution being given to meet her caloric requirements. After a week's time she showed signs of rousing, accompanied by manifest evidences of irritability. Within 10 days of operation it was apparent that she was aware of the presence of people about her. It was evident that she could hear them. Her speech at this juncture was hesitant; she could repeat words and terms of endearment seemed to elicit a suggestion of an earlier familiarity with them; that her memory of certain previous experiences was retained was evident 3 weeks after operation when asked one morning if she could sing, she sang sweetly and without faltering or hesitation, "Jesus loves me, this I know, for the Bible tells me

¹As a result of this experience, work is now in progress in this clinic with the help of Dr. A. O. Nier of the Department of Physics and Dr. Allan Hlemingway of the Department of Physiology to develop a portable spectrophotograph to aid the anesthetist in determining the concentration of CO₂ in the alveolar air during operative procedures.

so." Hearing sense of smell and speech appeared to return in that order. While we waited from day to day with mixed feelings of hope and despair for encouraging signs of improvement it had been urged that steps be taken to commit the child to an institution—a suggestion which the parents as well as the surgeons resisted. Four to 5 weeks after operation it was obvious that the child could discern darkness from light. Her speech improved gradually and the movements of her extremities became more co-ordinated. Nine weeks after operation she was dismissed from the hospital returning for occasional observation in the outpatient clinic. Ability to differentiate colors and to distinguish circles from triangles and other evidences of returning vision appeared months after the cardiac arrest. During the past school year the patient made her way to school unaided.

SUMMARY

In all operative division of the ductus has been done in 69 consecutive cases.¹ The only death in the series concerned a patient of 31

¹At the present time (August 30, 1948) 8 additional patients have been operated upon. (thoracic complication. Ligature rather than division as done in one of them, Mrs. M. M. University Hospital No. 78633, 3, April 31, for this patient had condition many months very much like that reported in the instance of Mrs. O. L. (780,607) above. Ligature was done on February 5, 1948 and no evidence of recanalization has appeared.

years with subacute bacterial endocarditis auricular fibrillation and severe cardiac decompensation in whom a granulomatous plaque beneath the pulmonic end of a broad ductus made ligature difficult after division of the ductus. Touroff's suggestion that ligature is a wiser expedient than division in such instances is borne out in this experience.

A technique for dissection and division of the ductus constituting essentially minor variations of the technique described by Gross is detailed herein.

The average postoperative hospital stay save for the patient with a complication has been less than a week.

FRACTURES OF THE UPPER END OF THE RADIUS AND ULNA

FRANK D DICKSON M D F.A.C.S. Kansas City Missouri

A FRACTURE into the elbow joint is always a threat to the usefulness of this articulation because serious impairment of function so frequently results. The importance of the elbow joint need not be elaborated upon, as it is common knowledge that the loss of or serious interference with, flexion and extension or pronation and supination movements which take place in this joint, may interfere with the ability to earn a livelihood and the performance of many acts necessary to satisfactory and gracious living.

Fractures into the elbow joint numerically comprise an important group, as they make up a considerable portion of the fractures which must be dealt with both in private practice and in large fracture clinics. Supracondylar fractures are the most frequent fractures of childhood and adolescence, and comminuted fractures of the lower end of the humerus are increasing in frequency in the youth and adult groups largely because of the reprehensible habit of driving an automobile with an elbow projecting from the window, a habit which is quite prevalent today. When to these two groups are added fractures of the upper end of the radius and ulna it is evident that there is a rather formidable list of fractures which may be expected to result in some permanent impairment of the function of the elbow joint. Philip Wilson in the Fracture Oration of 1932 under the title Fractures and Dislocations of the Elbow, discussed injuries to this region in a very comprehensive way and left little of importance to be added. The chief emphasis in that analysis, however, was placed upon fractures of the lower end of the humerus; this presentation which deals only with fractures of the upper end of the radius and ulna should serve to bring into focus the part played by fractures of these elements of the elbow joint

in the production of pathology which causes impairment in its function.

Anatomically by the term 'elbow joint' is meant the articulation between the lower end of the humerus above and the ulna and head of the radius below (Fig 1). The articulation between the ulna and the head of the radius forms the superior radioulnar joint, which does not belong to the elbow joint proper. However the movements of flexion and extension, which take place in the elbow joint, and the movements of pronation and supination which take place between the radius and the ulna centered in the superior radioulnar joint, are so intimately related that from a functional point of view these two joints must be considered as one. The intricate movements the forearm and hand are called upon to carry out are possible only through coordination of the movements of flexion and extension and pronation and supination, and this coordination depends not only upon the proper alignment of the ulna and the head of the radius with the lower end of the humerus but also upon proper alignment between the head of the radius and the ulna. Any disarrangement in these alignments no matter where it occurs, can not fail to impair function in the elbow joint either in the direction of flexion and extension or pronation and supination or both. It is with those fractures of the upper end of the radius and ulna which interfere with the proper alignment of the bones which comprise the functional elbow joint that this discussion is concerned.

The fractures to be considered are (1) fractures of the head of the radius (2) fractures of the olecranon (3) fractures of the upper end of the ulna with dislocation of the head of the radius (Monteggia fracture).

FRACTURES OF THE HEAD OF THE RADIUS

Fracture of the head of the radius results from a fall on the outstretched hand. When such an accident occurs the elbow is almost

¹Fracture oration presented before the Clinical Congress of The American College of Surgeons, New York, September 8-11 1932

completely extended and the radius pronated so that the anterolateral section of the head of the radius is driven with considerable violence against the capitellum of the humerus. The damage sustained by the head of the radius depends upon the force of the impact usually it is possible to differentiate three types of fracture of the radial head by roentgenogram (1) a fissure fracture with no or mild displacement (2) a marginal fracture with displacement of a sector of bone (3) a comminuted fracture involving most of the head of the radius

Fracture of the head of the radius should be readily diagnosed as the symptoms complained of are classic these are tenderness over the head of the radius on palpation limitation of extension of the elbow joint with onset of acute pain if extension is even mildly forced, and limitation of pronation and supination with production of pain if these movements are persisted in. While the symptoms enumerated are common to all three types of fracture of the head of the radius, the form of treatment indicated varies with the type to be dealt with this fact must be held constantly in mind in planning the management of radial head fractures.

Treatment It is important to remember that a fracture of the head of the radius is not the trivial injury it may appear and that intelligent treatment based on clear roentgenograms carefully studied is demanded if permanent impairment of elbow joint function is to be avoided. Furthermore injury to the cartilage of the capitellum and even fracture of the capitellum the result of the impact of the head of the radius against it and ligamentous damage are complications that not infrequently are associated with this fracture and such possible complications must be considered in any plan of treatment decided upon. For clarity the treatment of each type will be discussed separately.

Fissure fractures (Fig 2) The injury is a subperiosteal crack which separates slightly a sector of bone from the radial head usually from its outer border. In young individuals the injury may consist in a tilting of the head on the neck. Although the displacement in this type of fracture is minimal if permitted to

persist an incongruence between the head of the radius and the capitellum will develop and result in permanent limitation of extension and pronation and supination. Such fractures should be treated by supporting the elbow at a right angle in a sling for a week to 10 days to allow the traumatic reaction to subside at the end of this period the sling should be removed four or five times a day and active flexion and extension and pronation and supination carried out by the patient. There should be no passive manipulation or forcible stretching at any time as such maneuvers are likely to cause a serofibrous reaction and the formation of calcareous deposits in the capsule of the joint with permanent impairment of function. On the other hand active movements which the patient himself controls will be guarded and so unlikely to be forced sufficiently to cause an unfavorable reaction. The purpose of daily movement is to mold the distorted radial head to the capitellum while the fracture is still in a plastic state by so doing even if an anatomical reduction is not secured, a satisfactorily functioning joint results. At the end of 3 weeks, the sling may be discarded and use continued until healing is complete this usually requires from 8 to 10 weeks. A few degrees of limitation of extension will usually persist but this is not incapacitating.

Marginal fractures with displacement (Fig 3) In this type of fracture of the head of the radius a sector of bone usually from the lateral anterior part of the head is depressed and impacted or tilted out of position or completely separated from the main fragment. When the fragment is impacted or tilted out of place but still in contact with the remainder of the head, conservative treatment is indicated. Such conservative treatment is the same as that used in type one namely immobilization of the elbow at right angles for 10 days to 2 weeks preferably in a posterior plaster mold in this fracture for more complete immobilization. At the end of this time the splint may be replaced by a sling and active flexion and extension and pronation and supination movements carried out by the patient five or six times daily. Again it should be emphasized that passive manipulation and forcible stretching are harmful and may lead to permanent interfer-

Fig. 1 The elbow and superior radioulnar joints.

ence with function. The same molding of the distorted head to the capitellum is brought about by early guarded movements in this fracture as in type one and an essentially normal range of joint motion will result.

When the fractured off sector is completely separated from the main fragment (Fig. 4) conservative measures should be abandoned and surgery resorted to as ossification of the intervening hematoma produces an irregularly shaped head which will not articulate properly with the capitellum or the ulna and limitation of both flexion and extension and pronation and supination will follow. The surgery carried out depends upon the degree of damage suffered by the radial head. If the fragment is but a small sector and the remainder of the head is intact, simple removal of the loose fragment is all that is necessary. If the fractured sector comprises a large segment of the head (Fig. 5) or if there is any degree of comminution present, the entire head should be resected as arthritic changes will certainly develop later.

When dealing with fractures falling in type 2 it is necessary to make the decision early as to whether they should be treated conservatively or by surgery. If arthrotomy is to be performed and the fragment removed or the head resected, it should be done within 10 days

of the injury. Delay for several weeks will almost invariably give a less satisfactory result with definite impairment of function. As in type 1, some limitation of extension and perhaps slight limitation of pronation and supination are to be anticipated.

Comminuted fracture of the head of the radius (Fig. 6) In this type the head of the radius is broken up into a number of fragments which lie loose in the joint or the head is entirely fractured off and completely turned on itself. Conservative measures have no place in the treatment of such fractures as dense adhesions between the fragments and the capsule rapidly form. Excision of the entire radial head is necessary if joint function is to be preserved (Fig. 7). The optimum time for surgery is within 7 to 10 days of the injury; for if surgery is delayed for several weeks or months, limitation of joint motion will already have developed and late removal of the head seldom improves the result.

When the radial head is to be removed, the incision should be placed over the head of the radius posterior to the extensor muscle mass where the field is almost bloodless. The neck of the radius should be cut across cleanly with an osteotome at the level of the upper border of the orbicular ligament. The raw surface of

completely extended and the radius pronated that the anterolateral section of the head of the radius is driven with considerable violence against the capitellum of the humerus. The damage sustained by the head of the radius depends upon the force of the impact usually it is possible to differentiate three types of fracture of the radial head by roentgenogram: (1) a pure fracture with no or mild displacement; (2) a marginal fracture with displacement of a sector of bone; (3) a comminuted fracture involving most of the head of the radius.

Fracture of the head of the radius should be readily diagnosed as the symptoms complain of are classic: these are tenderness over the head of the radius on palpation, limitation of extension of the elbow joint with onset of acute pain if extension is even mildly forced, and limitation of pronation and supination with production of pain if these movements are performed in. While the symptoms enumerated are common to all three types of fracture of the head of the radius, the form of treatment indicated varies with the type to be dealt with. This fact must be held constantly in mind in planning the management of radial head fractures.

Treatment. It is important to remember that a fracture of the head of the radius is not a trivial injury; it may appear and that intelligent treatment based on clear roentgenograms carefully studied is demanded if permanent impairment of elbow joint function is to be avoided. Furthermore, injury to the cartilage of the capitellum and even fracture of the capsule—the result of the impact of the head of the radius against it and ligamentous damage—complications that not infrequently are associated with this fracture and such possible complications must be considered in any plan of treatment decided upon. For clarity the treatment of each type will be discussed separately.

Crack fractures (Fig. 2). The injury is a periosteal crack which separates slightly a sector of bone from the radial head usually on its outer border. In young individuals injury may consist in a tilting of the head of the neck. Although the displacement in this type of fracture is minimal, if permitted to

persist an incongruence between the head of the radius and the capitellum will develop and result in permanent limitation of extension and pronation and supination. Such fractures should be treated by supporting the elbow at a right angle in a sling for a week to 10 days to allow the traumatic reaction to subside; at the end of this period the sling should be removed four or five times a day and active flexion and extension and pronation and supination carried out by the patient. There should be no passive manipulation or forcible stretching at any time as such maneuvers are likely to cause a serofibrous reaction and the formation of calcareous deposits in the capsule of the joint with permanent impairment of function. On the other hand active movements which the patient himself controls will be guarded and so unlikely to be forced sufficiently to cause an unfavorable reaction. The purpose of daily movement is to mold the distorted radial head to the capitellum while the fracture is still in a plastic state; by so doing even if an anatomical reduction is not secured a satisfactory functioning joint results. At the end of 3 weeks, the sling may be discarded and use continued until healing is complete; this usually requires from 8 to 10 weeks. A few degrees of limitation of extension will usually persist but this is not incapacitating.

Marginal fractures with displacement (Fig. 3). In this type of fracture of the head of the radius, a sector of bone—usually from the lateral anterior part of the head—is depressed and impacted or tilted out of position or completely separated from the main fragment. When the fragment is impacted or tilted out of place but still in contact with the remainder of the head, conservative treatment is indicated. Such conservative treatment is the same as that used in type one—namely immobilization of the elbow at right angles for 10 days to 3 weeks, preferably in a posterior plaster mold in this fracture for more complete immobilization. At the end of this time the splint may be replaced by a sling and active flexion and extension and pronation and supination movements carried out by the patient five or six times daily. Again it should be emphasized that passive manipulation and forcible stretching are harmful and may lead to permanent interfer-

Fig 1 The elbow and superior radioulnar joints.

ence with function. The same molding of the distorted head to the capitellum is brought about by early guarded movements in this fracture as in type one, and an essentially normal range of joint motion will result.

When the fractured-off sector is completely separated from the main fragment (Fig 4) conservative measures should be abandoned and surgery resorted to as ossification of the intervening hematoma produces an irregularly shaped head which will not articulate properly with the capitellum or the ulna and limitation of both flexion and extension and pronation and supination will follow. The surgery carried out depends upon the degree of damage suffered by the radial head. If the fragment is but a small sector and the remainder of the head is intact, simple removal of the loose fragment is all that is necessary. If the fractured sector comprises a large segment of the head (Fig 5) or if there is any degree of comminution present, the entire head should be resected as arthritic changes will certainly develop later.

When dealing with fractures falling in type 2 it is necessary to make the decision early as to whether they should be treated conservatively or by surgery. If arthrotomy is to be performed and the fragment removed or the head resected, it should be done within 10 days

of the injury. Delay for several weeks will almost invariably give a less satisfactory result with definite impairment of function. As in type 1, some limitation of extension and perhaps slight limitation of pronation and supination are to be anticipated.

Comminuted fracture of the head of the radius (Fig 6) In this type the head of the radius is broken up into a number of fragments which lie loose in the joint or the head is entirely fractured off and completely turned on itself. Conservative measures have no place in the treatment of such fractures as dense adhesions between the fragments and the capsule rapidly form. Excision of the entire radial head is necessary if joint function is to be preserved (Fig 7). The optimum time for surgery is within 7 to 10 days of the injury, for if surgery is delayed for several weeks or months, limitation of joint motion will already have developed and late removal of the head seldom improves the result.

When the radial head is to be removed, the incision should be placed over the head of the radius posterior to the extensor muscle mass where the field is almost bloodless. The neck of the radius should be cut across cleanly with an osteotome at the level of the upper border of the orbicular ligament. The raw surface of

completely extended and the radius pronated so that the anterolateral section of the head of the radius is driven with considerable violence against the capitellum of the humerus. The damage sustained by the head of the radius depends upon the force of the impact usually it is possible to differentiate three types of fracture of the radial head by roentgenogram (1) a fissure fracture with no or mild displacement (2) a marginal fracture with displacement of a sector of bone (3) a comminuted fracture involving most of the head of the radius.

Fracture of the head of the radius should be readily diagnosed as the symptoms complained of are classic these are tenderness over the head of the radius on palpation limitation of extension of the elbow joint with onset of acute pain if extension is even mildly forced and limitation of pronation and supination with production of pain if these movements are persisted in. While the symptoms enumerated are common to all three types of fracture of the head of the radius the form of treatment indicated varies with the type to be dealt with this fact must be held constantly in mind in planning the management of radial head fractures.

Treatment It is important to remember that a fracture of the head of the radius is not the trivial injury it may appear and that intelligent treatment based on clear roentgenograms carefully studied is demanded if permanent impairment of elbow joint function is to be avoided. Furthermore injury to the cartilage of the capitellum and even fracture of the capitellum the result of the impact of the head of the radius against it and ligamentous damage are complications that not infrequently are associated with this fracture and such possible complications must be considered in any plan of treatment decided upon. For clarity the treatment of each type will be discussed separately.

Fissure fractures (Fig. 2) The injury is a subperiosteal crack which separates slightly a sector of bone from the radial head usually from its outer border. In young individuals the injury may consist in a tilting of the head on the neck. Although the displacement in this type of fracture is minimal if permitted to

persist an incongruence between the head of the radius and the capitellum will develop and result in permanent limitation of extension and pronation and supination. Such fractures should be treated by supporting the elbow at a right angle in a sling for a week to 10 days to allow the traumatic reaction to subside at the end of this period the sling should be removed four or five times a day and active flexion and extension and pronation and supination carried out by the patient. There should be no passive manipulation or forcible stretching at any time as such maneuvers are likely to cause a serofibrous reaction and the formation of calcareous deposits in the capsule of the joint with permanent impairment of function. On the other hand active movements, which the patient himself controls will be guarded and so unlikely to be forced sufficiently to cause an unfavorable reaction. The purpose of daily movement is to mold the distorted radial head to the capitellum while the fracture is still in a plastic state by so doing even if an anatomical reduction is not secured a satisfactory functioning joint results. At the end of 3 weeks the sling may be discarded and use continued until healing is complete this usually requires from 8 to 10 weeks. A few degrees of limitation of extension will usually persist but this is not incapacitating.

Marginal fractures with displacement (Fig. 3)

In this type of fracture of the head of the radius, a sector of bone usually from the lateral-anterior part of the head is depressed and impacted or tilted out of position or completely separated from the main fragment. When the fragment is impacted or tilted out of place but still in contact with the remainder of the head, conservative treatment is indicated. Such conservative treatment is the same as that used in type one namely immobilization of the elbow at right angles for 10 days to 2 weeks preferably in a posterior plaster mold in this fracture for more complete immobilization. At the end of this time the splint may be replaced by a sling and active flexion and extension and pronation and supination movements carried out by the patient five or six times daily. Again it should be emphasized that passive manipulation and forcible stretching are harmful and may lead to permanent interfer-

Fig. 1 The elbow and superior radioulnar joints.

ence with function. The same molding of the distorted head to the capitellum is brought about by early guarded movements in this fracture as in type one and an essentially normal range of joint motion will result.

When the fractured-off sector is completely separated from the main fragment (Fig. 4) conservative measures should be abandoned and surgery resorted to as ossification of the intervening hematoma produces an irregularly shaped head which will not articulate properly with the capitellum or the ulna and limitation of both flexion and extension and pronation and supination will follow. The surgery carried out depends upon the degree of damage suffered by the radial head. If the fragment is but a small sector and the remainder of the head is intact, simple removal of the loose fragment is all that is necessary. If the fractured sector comprises a large segment of the head (Fig. 5) or if there is any degree of comminution present, the entire head should be resected as arthritic changes will certainly develop later.

When dealing with fractures falling in type 2 it is necessary to make the decision early as to whether they should be treated conservatively or by surgery. If arthrotomy is to be performed and the fragment removed or the head resected, it should be done within 10 days

of the injury. Delay for several weeks will almost invariably give a less satisfactory result with definite impairment of function. As in type 1, some limitation of extension and perhaps slight limitation of pronation and supination are to be anticipated.

Comminuted fracture of the head of the radius (Fig. 6) In this type the head of the radius is broken up into a number of fragments which lie loose in the joint or the head is entirely fractured off and completely turned on itself. Conservative measures have no place in the treatment of such fractures, as dense adhesions between the fragments and the capsule rapidly form. Excision of the entire radial head is necessary if joint function is to be preserved (Fig. 7). The optimum time for surgery is within 7 to 10 days of the injury, for if surgery is delayed for several weeks or months, limitation of joint motion will already have developed and late removal of the head seldom improves the result.

When the radial head is to be removed, the incision should be placed over the head of the radius posterior to the extensor muscle mass where the field is almost bloodless. The neck of the radius should be cut across cleanly with an osteotome at the level of the upper border of the orbicular ligament. The raw surface of

the neck should be covered with a flap comprised of stripped back periosteum or flaps dissected from surrounding soft tissues to seal it off and to prevent proliferative changes at this point. The most frequent error made is failure to resect far enough distally. When this error is made the expanded part of the neck is left behind and adhesions between it and the ulna frequently form and limit pronation and supination. Placing the incision too far forward brings it near the posterior interosseous nerve damage to which will result in wrist drop.

FRACTURES OF THE OLECRANON

Fractures of the olecranon may be caused by direct violence such as a fall or blow on the tip of the elbow or by indirect violence in the form of forcible flexion of the elbow against the strong resistance of the powerful triceps muscle. Some fractures of the olecranon result in slight or no separation of the fragments (Fig 8) such fractures cause little disturbance in the elbow and present no problem in treatment. When however there is separation of the fragments or even as little as one-fourth inch a definite problem in treatment is involved (Fig 9). With displacement of the proximal fragment the triceps tendon which is attached to it is relaxed and loses its power to extend the elbow actively. Permanent relaxation of the triceps tendon which must occur unless the fragments are brought into contact and a firm bony union secured will result in continuing weakness of active extension of the elbow which prevents reaching for objects above the shoulder level and weakens the ability to push against resistance. If the fragments are not brought into apposition and a fibrous union occurs, degenerative arthritic changes in the articular cartilage of the elbow joint may be anticipated and limitation of flexion and extension will occur in a very considerable percentage of cases. Even if bony union takes place in spite of separation of the fragments an incongruence of the joint surface develops and serious limitation of flexion and extension is the usual outcome. It may be stated then that fractures of the olecranon like fractures of the head of the radius can not be considered to be trivial injuries but on the contrary may lead to serious disability in the elbow joint.

Treatment There are two objectives to be sought for in treatment of fractures of the olecranon (1) the restoration of normal length and tension of the triceps muscle so that it may function properly (2) the securing of a normal contour of the upper end of the ulna, which must articulate accurately both with the trochlear surface of the humerus and the olecranon fossa, into which the olecranon fits when the elbow is extended, if normal function is to be restored. Unless both these objectives are attained, normal or even useful elbow function will be jeopardized.

Fractures of the olecranon without separation can be dismissed with brief comment. If flexion of the elbow does not cause separation of the fragments, the elbow should be treated by immobilization in a posterior plaster mold in right angle flexion. If flexion causes even the slightest separation the fracture should be treated in extension in an anterior plaster mold extending from the axilla to the palm. If the extended position is necessary it is desirable to initiate flexion movements as early as possible but such movements should not be started too early. Many advise starting flexion in 3 weeks our experience however has been that this is too early and that 5 weeks is as soon as flexion exercises should be carried out. Separation of the fragments with disastrous results has occurred in several cases which have come under our observation in which early motion had been insisted upon. Recovery of motion should be achieved by active movements carried out by the patient. Passive movements and forcible stretching are contraindicated because of the danger of setting up a fibrosis in the capsule. Ample time should be allowed for recovery as some limitation of movement may persist for 8 or 10 months.

Fractures of the olecranon with separation of the fragments present quite a different problem in treatment. Restoration of length and tone to the triceps muscle and proper modeling of the upper end of the ulna must be attained to insure a satisfactory outcome. If extension of the elbow and manipulation of the proximal fragment do not result in perfect apposition, surgery must be resorted to in practically all cases. One other method of closed reduction

and immobilization may be employed when the olecranon fragment is large (Fig. 10). In this method the fragment is transfixed with a Steinmann pin and levered into position. After reduction has been accomplished the pin is driven down into the ulna a sufficient distance to anchor firmly the fragment in position. A plaster cast should then be applied with the elbow at right angles. The end of the Steinmann pin is allowed to project through the cast and fixed in position with a few turns of plaster. When this method is used the alignment of the fracture should be checked by fluoroscope or roentgenograms before the pin

is driven home in the ulna. Our experience indicates that the pin should be driven into the ulna in such a way as to engage the cortex of the bone rather than pass down in the medullary canal as better fixation is secured. Plaster fixation should be maintained for 5 weeks after which time the pin may be removed and active exercises started. This form of treatment has given satisfactory results in 5 cases in which it was used and unsatisfactory results in 3 cases. The method is not without drawbacks and should be used only in selected cases. Frequent check of position by roentgenogram should be made during the first 2 weeks. The

unsatisfactory results were those in which arthritic changes occurred with definite limitation of motion (Fig. 11).

Practically all fractures of the olecranon with separation are best treated by surgery since active extension of the elbow can be expected only if the triceps is re-united to the ulna without lengthening of its tendon and normal flexion and extension only with accurately fitting joint surfaces in the hinge between the ulna and the trochlea of the humerus and accurate seating of the olecranon in the olecranon fossa. The normal length and tone of the triceps can be restored by one of two surgical procedures: (1) open reduction of the fracture with the use of internal fixation so that bony union in perfect position will result or (2) by exci-

tion of the olecranon fragment and reattachment of the triceps tendon with its lateral aponeurosis to the upper end of the ulna.

When open reduction is chosen fascia lata should be used as the fixation material. Fine stainless steel wire may be used but screws and nails are less desirable because of the early and late tissue reaction which they may excite. The fracture is exposed and cleaned of all interposing tendon fibers which may have fallen between the fragments and interfere with bony contact. A hole should be drilled transversely in the distal fragment of the ulna and a suture passed through the drill hole and around the proximal fragment engaging the entire triceps insertion in which it is buried (Fig. 12). This suture should cross over the fracture so that

Fig 12

when tied it will approximate the fragments and prevent tilting and lateral displacement. If the olecranon fragment is large it is better to drill a tunnel through each fragment and add a second suture passing directly from drill hole to drill hole (Fig 13). The elbow should

then be gently flexed to about a right angle and the position of the fragments carefully checked to see that accurate reduction is maintained. The elbow should be immobilized in plaster at right angles for 5 to 6 weeks. Active movement is carried out as in the closed method.

unsatisfactory results were those in which arthritic changes occurred with definite limitation of motion (Fig. 11).

Practically all fractures of the olecranon with separation are best treated by surgery since active extension of the elbow can be expected only if the triceps is re-united to the ulna without lengthening of its tendon and normal flexion and extension only with accurately fitting joint surfaces in the hinge between the ulna and the trochlea of the humerus and accurate seating of the olecranon in the olecranon fossa. The normal length and tone of the triceps can be restored by one of two surgical procedures: (1) open reduction of the fracture with the use of internal fixation so that bony union in perfect position will result, or (2) by excis-

ion of the olecranon fragment and reattachment of the triceps tendon with its lateral aponeurosis to the upper end of the ulna.

When open reduction is chosen, fascia lata should be used as the fixation material. Fine stainless steel wire may be used, but screws and nails are less desirable because of the early and late tissue reaction which they may excite. The fracture is exposed and cleaned of all interposing tendon fibers which may have fallen between the fragments and interfere with bony contact. A hole should be drilled transversely in the distal fragment of the ulna and a suture passed through the drill hole and around the proximal fragment, engaging the entire triceps insertion in which it is buried (Fig. 12). This suture should cross over the fracture so that

Fig 12

Fig 13.

Fig 4

when tied it will approximate the fragments and prevent tilting and lateral displacement. If the olecranon fragment is large it is better to drill a tunnel through each fragment and add a second suture passing directly from drill hole to drill hole (Fig 13). The elbow should

then be gently flexed to about a right angle and the position of the fragments carefully checked to see that accurate reduction is maintained. The elbow should be immobilized in plaster at right angles for 5 to 6 weeks. Active movement is carried out as in the closed method.

Fig. 5. Primary resection of proximal fragment. Normal function in 8 weeks.

Excision of the olecranon fragment is, in our experience, a much simpler and more certain method of treating fractures of the olecranon with separation than open reduction. Even with accurate reposition, malalignment of the proximal fragment may develop in the course of healing (Fig. 14). This displacement may prevent the tip of the olecranon from seating properly in the olecranon fossa and limited extension follow. Degeneration of the articular cartilage on the ulna and even on the trochlea may take place; the result of the trauma suffered at the time of injury, and such degenerative changes produce a traumatic arthritis in the elbow joint with limitation of flexion and

extension although alignment may be perfect is maintained. When the olecranon fragment is excised, all danger of any incongruence between the olecranon and the olecranon fossa is removed, and the danger of traumatic arthritis due to degenerative changes in the articular cartilage of the ulna is eliminated. Return of normal flexion and extension movements takes place rapidly, and the convalescent period is markedly shortened (Fig. 15).

The essential part of the operation is not the excision of the olecranon fragment but reattachment of the triceps tendon. The fragment should be shelled out by close sharp dissection, preserving all attachments of the triceps tendon. Two drill holes should be made in the proximal end of the ulna. Mattress sutures of fascia lata are placed in the triceps tendon and passed through the drill holes in the ulna, firmly anchoring the tendon to bone. Additional fixation is secured by suturing with catgut the lateral margins of the triceps tendon to the fascia on each side of the ulna. The elbow should be immobilized in plaster at right angles for 10 days to 2 weeks, and then active exercises should be carried out to restore use which will usually return rapidly. There is no danger of forward displacement of the ulna even if quite a large fragment must be removed, as the strong triceps muscle prevents this. Only failure to reattach the triceps tendon properly and adequately will allow for forward displacement to occur. We have found resection so satisfactory that it is used routine-

ly in our clinic unless there are complicating factors which make it undesirable

MONTEGGIA FRACTURES

Fracture of the upper end of the ulna with dislocation of the head of the radius first described by Monteggia a century ago is one of the most disastrous fractures which occurs about the elbow joint so far as impairment of elbow function is concerned. Statistics indicate that in approximately 90 to 95 per cent of cases permanent disability of a high grade follows this fracture. The typical Monteggia fracture (Fig. 16) of the ulna occurs 3 to 4 inches below the olecranon but the line of fracture may lie closer to the joint (Fig. 17). The solution in the continuity of the ulna is complicated by rupture of the orbicular ligament and dislocation of the head of the radius. Satisfactory reduction and maintenance of reduction of the fracture of the ulna are difficult

Fig. 19 Diagram of method of closed reduction of Monteggia fracture

Fig. 20 The result of inadequate internal fixation wire loop failed to hold fracture in place.

so that malunion is frequent and extensive damage to the orbicular ligament often makes it impossible to maintain the head of the radius in position after it is reduced. Malunion of the ulna and permanent dislocation of the head of the radius mean an elbow joint in which both flexion and extension and pronation and supination will be permanently limited and to a serious extent (Fig. 18).

Treatment A Monteggia fracture of the usual type is reduced by flexing the elbow apply

Fig. 1 Late resection of the head of the radius in Monteggia fracture with practically normal function

ing traction and manipulation (Fig. 19). Unfortunately these maneuvers give a satisfactory reduction of the fracture of the ulna and replacement of the dislocation of the head of the radius in comparatively few cases and in these there is a strong tendency toward displacement. Very few Monteggia fractures are successfully reduced by manipulation and open reduction with internal fixation is demanded from the start. The fracture should be exposed, accurate reduction secured and the fragments immobilized with an adequate bone plate (Fig. 20). Perfect reduction of the ulnar fracture will, as a rule, bring about replacement of the dislocated head of the radius (Fig. 21). If the head of the radius fails to reduce, it should be manipulated into place; it should not be exposed and open reduction and repair of the orbicular ligament undertaken. Open replacement of the dislocated radial head if carried out at the same operation as plating of the ulna almost invariably leads to ankylosis or limitation of motion in the upper radio-ulnar joint because of ossification about the head and neck of the radius which usually follows. *Watson Jones* considers this ossification to be due to the deposit of calcium in the hematoma disseminated into the muscles and ligaments by surgical interference. If the displacement of the head of the radius can not be corrected by reduction of the ulna and manipulation, it should be allowed to remain displaced and 2 or 3 months later the head should be resected. Contrary to what occurs in fractures of the head of the radius, late removal of the dislocated radial head gives excellent function as regards flexion and extension and pro-

nation and supination. In a certain number of cases the head of the radius will replace when the ulna is brought into alignment but within a few days or a week or two it will redislocate because the orbicular ligament fails to repair itself (Fig. 22). When this complication occurs, it is best to do nothing about it for 2 or 3 months and then resect the radial head (Fig. 23). There are many with wide fracture experience who prefer to reconstruct the orbicular ligament rather than resect the head of the radius; if this is done it should be postponed for at least 2 months as is resection of the head and for the same reason. In our experience late resection of the radial head has given more satisfactory results than attempts to reconstruct the orbicular ligament as it is rarely possible to anchor the head of the radius securely in place by an artificial ligament and the radioulnar joint is so relaxed that it may be unreliable, painful and later develop arthritis.

The elbow joint from childhood is vulnerable to injury. The mechanics of the functional elbow joint are so complex that any injury which interferes with the proper alignment of its component parts can cause impairment of function of serious degree. Because this is so, fractures which involve the upper end of the radius and ulna, important elements in the joint, demand careful appraisal and the selection of that form of treatment which will insure restoration of the most advantageous relations between the articular surface of the ulna, the head of the radius, and the lower articular surface of the humerus. Anatomical alignment is important but a satisfactorily functioning elbow joint is more so and restoration of function must be the aim of treatment. The first step to this end is understanding that no fracture which enters the elbow joint is a trivial injury but one which carries with it the possibility of permanent impairment. The second step is never to overlook the susceptibility of the elbow joint to form adhesions and so avoid in the after treatment of elbow fractures, including those of the upper end of the radius and ulna, the use of passive motion and forceful manipulation which promote the formation of adhesions and these always result in limitation of movement in one or more directions with varying degrees of disability.

ONL HUNDRED CASES OF CONGENITAL ABSENCE OF THE VAGINA

ALLEN L. BRYAN M.D. JOSEPH A. NIGRO M.D. and
VIRGIL S. COUNSELLER M.D. F.A.C.S. Rochester Minnesota

THE primary purpose of this article is to compare the various methods of surgical treatment for congenital absence of the vagina. During the course of time many procedures have been utilized with varying degrees of success but only relatively recently has an entirely satisfactory method been employed which is simple, entails minimal morbidity and mortality, and produces a high percentage of good results.

We are including 14 operations done according to the Baldwin technique, 1 according to the Falls method, 1 of iodoform gauze packing, 70 McIndoe procedures in which split skin grafts are employed, and 14 operations performed according to the technique popularized at the clinic by one of us (V. S. C.) which consists of simple dissection and insertion of a mold. Data on 76 of these cases were presented by the senior author (V. S. C.) at the meeting of the American Medical Association at Atlantic City, New Jersey, June 9 to 14, 1947.

EMBRYOLOGY

Development of the vagina varies from partial to total. This structure is derived from the (1) muellerian ducts (18-32), (2) wolffian ducts, and (3) urogenital sinus (29-37-40-51). Numerous microscopic sections made on human embryos during growth have materially aided embryologists. At 8 millimeters the muellerian ducts appear as an evagination of the celomic cavity lateral to the upper portion of the wolffian ducts. The caudal portion of the muellerian ducts forms a tube with a solid tip which burrows itself through the mesenchyme of the urogenital fold crossing the wolffian ducts anteriorly and at the caudal end of the mesonephros. At 30 millimeters the caudal tips of the muellerian ducts fuse and reach the posterior wall of the urogenital sinus,

pushing it forward and forming the muellerian tubercle. With the distal fusion of the muellerian ducts, the uterovaginal canal is formed. The wolffian ducts have kept pace with the muellerian system but at 56 millimeters begin showing signs of involution. Approximately at this time there is a great intermingling of cells of the urogenital sinus, wolffian ducts and muellerian ducts, and here is where controversy persists as to what group of cells proliferates to predominate in the formation of the vagina. At 63 millimeters the muellerian tubercle gives way to the bilateral sinovaginal bulbs formed by the evagination of the posterior wall of the urogenital sinus. The growing of the sinovaginal bulbs and the transformation of the columnar epithelium to stratified epithelium of the lower portion of the uterovaginal canal results in the formation of a primitive vaginal plate. The vaginal plate increases in size and proliferating cells invade the surrounding mesenchyme. The epithelial activity begins at the caudal end. This proliferation forms a solid vaginal cord. The cells in the center of the solid cord undergo involution and desquamation, thereby forming the vaginal canal which first appears in embryos of 150 to 200 millimeters trunk length. This canal communicates with the cervical canal above and the hymenal foramen below. (43)

SURGICAL PROCEDURES USED IN RECONSTRUCTING AN ARTIFICIAL VAGINA

Bowel transplants. In this country when a portion of bowel is to be used as the new artificial vagina, the Baldwin technique has been favored most. In 1904 Baldwin (3, 4) described a method for using the ileum as a transplant but did not have a chance to try it until 1907. The method proposed was to excise a loop of ileum 10 inches long (25 cm.) and to reunite the bowel by an end-to-end anastomosis. He then dissected between the bladder

(From Counseller V. S. Congenital anomalies with particular reference to cryptorchidism, hypospadias and congenital absence of vagina. *J. Mich. M. Soc.* 938, 37 689-697. Fig. 4, p. 696.)

and rectum using a perineal approach pulled the middle of the isolated loop downward attached the upper end of the loop around the cervix and closed the other end. The abdomen was then closed. With the patient in the lithotomy position and the loop of bowel held in a forceps the bowel was opened up, cleansed, each limb was packed with iodoform gauze and the edges of the bowel were attached to the surrounding hymenal margins. After 2 weeks a clamp was placed on the double barrelled septum converting the two loops of bowel into one canal. In 1910 this procedure was modified by Mori, who used only one loop of bowel sutured to the vaginal introitus.

Previously, the rectum had been employed in repair of this condition as reported by Sneguireff in 1892, who made an incision from the coccyx to the anus and separated the rectum from the coccyx, which was excised. The intestine was ligated in two places and divided. The superior segment was sutured to the right of the coccygeal region and the inferior segment was brought down and its upper end closed. Two weeks later a second stage was done, in which the perineum was incised and the rectal mucous membrane was sutured to the adjacent parts. In 1910 Popow and in 1911 Schubert utilized methods similar to those used by Sneguireff.

Labial grafts. The first to use labial grafts to form an artificial vagina was Jewett in 1904, but Graves popularized this method in 1908 using two labial flaps and two thigh flaps over a glass form. When the skin pouch was almost completely sutured, the glass form was removed and the flaps invaginated and sutured to the depths of the vault. Davis and Cron modified Graves's method by using only labial flaps and by making their original perineal incision vertically rather than transversely. Falls in 1940 cut a disc 2 to 3 centimeters in diameter around the introitus, then undercut the edges and pushed the disc back by blunt dissection. Four skin flaps from the vulval opening were taken and their free end was sewed to the edges of the disc. This skin lined cavity was packed with gauze daily with moderate pressure until healing was complete. Meigs suggested tunneling between the bladder and rectum and then leaving a mold in place for 6

to 12 months, after which internal grafting according to the Graves method is carried out.

Grafts from thigh. In 1900 Beck reported use of skin flaps from the thigh after he had opened a tract between the bladder and rectum using both abdominal and perineal incisions. All the dissection was done extraperitoneally and after the passage which was created by the perineal approach met the prevesical space two skin flaps from the thigh were seized by forceps introduced through the superior abdominal opening, drawn up and sutured to the depth of the newly created vault. The vagina was then packed with iodoform gauze.

Frank and Geist (22) in 1927 modified the procedure. They outlined a flap along the inner surface of the thigh. The raw edges were turned in over a tube. Two weeks later the distal end of the tube graft was partially incised. A little later a canal was established by blunt dissection in the rectovesical septum, the distal end of the tube graft was completely separated and the graft was turned inside out with the skin inside over a vaginal plug. This graft was then sutured to the depth of the vault. Eight days later the proximal end of the original flap was completely separated from the donor area and the cut edges sutured to the vulval margin.

Grad in 1932 used several steps to swing his graft and the mold was not used until the procedure was completed. He resorted to split skin grafts to repair any resultant defects.

Free skin grafts. Heppner in 1872 made the first attempt to use this method but apparently without much success. Flynn, according to Flynn and Duckett, in 1915 used free skin grafts from the external genitalia to line the vaginal tract. An excellent result was obtained after repeated dilatations. In 1930 Kirschner and Wagner used a rubber sponge prosthesis covered with Thiersch grafts. The vaginal tract was drained by a rigid rubber tube which was inserted through the sponge. In 8 to 10 days the sponge was removed and dilatations were begun. In 1938 McIndoe and Banister reported a case of the satisfactory use of a Thiersch graft over a vaginal mold which was left in place 3 to 6 months until the contractile phase of the grafting process was

over. Emphasis was placed on long-continued use of the mold. Bonney and McIndoe in 1944 were able to establish regular menses in a girl with a bicornate uterus and no cervix by joining the two halves of the uterus over a mold with a graft. Each of these authors has done the operation in about 30 cases. In 1944 Counseller and Sluder reported 35 such cases.

Simple pressure. In 1938 Frank (21) found that operation to create an artificial vagina was unnecessary in some instances. Frank's method was modified in 1940 in such a way that dilatation was accomplished by manual pressure of graduated tubes inward against the perineum one half hour twice a day. Progress was noted in weekly office visits the first month and in semimonthly visits the second month. This, then, establishes a permanent vagina which sometimes attains a depth of 3½ inches (8.9 cm). Steinmetz in 1940 reported a case in which this method was used. In 1941 Campbell found that he could lengthen the vagina to 3 inches (7.6 cm) in 2 to 4 weeks by this method. He used catrin pessaries at night for the raw areas in the vagina. Dawson in 1945 got a satisfactory result in 1 case by the method of Frank in which the vagina attained a depth of 3¼ inches.

Simple reconstruction. In some instances simple pressure is not sufficient for a satisfactory result; however a very simple surgical procedure has been devised which consists simply of tunneling in the rectovesical septum using mainly blunt dissection and then allowing the epithelial buds in the tract to proliferate and line the new vagina (Fig. 1). The vaginal canal remains patent as a result of the extended use of a vaginal mold. This method has now been used at the clinic in 14 cases. It was tried unsuccessfully as long ago as 1817 by Dupuytren who used tampons in the tract to maintain patency. In 1935 Wells gave impetus to the simple surgical procedures when he used only petrolatum gauze which was changed every 2 days, to maintain patency in the dissected vaginal tract. Kanter in the same year used iodoform gauze for 10 days, after which a dilator was worn for a time. The results in both cases were good.

In 1938 Wharton (53) used a mold made of paraffin or balsa wood covered with a condom.

One patient had been treated 10 years previously with an excellent result; the other patient would not report after 1 month. Wharton ventured the opinion that the epithelium from the lower third of the vagina (urogenital sinus) formed a large part of the epithelium of the upper two-thirds of the vagina (muellerian ducts). In 1946 Wharton (54) published reports of cases in which he used a Thiersch graft over the mold. This was done in order to hasten epithelialization so as to avoid relying on the proliferative powers of the vaginal epithelial buds; also by this procedure a decrease in the formation of scar tissue could be obtained. In that communication 16 cases were reported from Johns Hopkins. Miller Willson, and Collins have used molds with and without Thiersch grafts and they have expressed preference for the latter method because in those cases in which it was used the vagina seemed softer, more pliable, and better epithelialized. Grafts were employed in 11 of their 17 cases. Twenty seven cases in which the dissection, no graft technique was used with good results have been reviewed by Wells, Word Emge and Miller and co-workers.

Miscellaneous procedures. Tissue from various sources has been relied upon to form a lining for the prepared vaginal tract with varying degrees of success. Among these are Douglas transplants of peritoneum (50), amniotic membranes (8), vernix caseosa (31), hernial sac (1), and heterogenous vaginal transplants (34).

Some surgeons do not prefer one method exclusively and use several of the previously described procedures. Sadler in 1941 reported 3 cases in one of which the vagina was made by the husband in his attempts at coitus, in another of which only simple pressure was required to dilate the canal, and in the third of which a Thiersch graft over a mold was used. In 1945 Brady presented 4 cases in the first case the Graves method was used, in the second a modified Graves technique was followed, in the third Wharton's technique was employed and in the fourth only dilatation without operation was required.

ANALYSIS OF CASES

Incidence. In 1572 this condition was described by Realdus Columbus. According to

Engstadt, vaginal aplasia occurs once in 5 000 births. Owens found only 6 cases in 125,000 female hospital admissions. The incidence in our series was 1 case of congenital absence of the vagina in every 4,000 female patients.

Age. Of the 100 consecutive patients seen at the clinic with congenital absence of the vagina who underwent surgical correction, the ages varied from 14 to 49 years. Sixty-four of the patients were within the age range of 17 through 26 years, the average being 23 years for the entire series.

Family history. Ninety-six patients gave a negative family history. One patient had a sister who had amenorrhea, another had a sister with amenorrhea and infantile genitalia, still another had a sister who menstruated only twice a year, and a fourth had a sister who had congenital absence of the vagina.

Menstrual history. Ninety-nine of the patients gave a history of amenorrhea. One patient had normal menses except that the flow was through the urethra and one had vicarious menses through the lungs and rectum. Ninety of the patients became aware of their condition after they had consulted their physician because of amenorrhea. Ten patients were not disturbed by the amenorrhea but complained of inability to have intercourse. Of the 99 patients with amenorrhea, 34 complained of periodic (usually monthly) cramps in the lower part of the abdomen. These cramps were occasionally severe and were the initiating factor in causing the patient to seek medical advice.

Physical findings. Of the 100 patients with congenital absence of the vagina, 2 had infantile external genitalia and no pubic hair. In 61 patients the medical examiner was unable to palpate tubes, ovaries or uterus, but because of the secondary sexual characteristics, it seemed that some ovarian tissue was undoubtedly present. In 10 of the 61 patients estrin levels in the urine were determined and found to be normal. In 19 patients tubes, ovaries and uterus were palpable. In 9 patients the uterus alone was palpable. In 9 patients tubes and ovaries alone were palpable. In 2 patients ovaries alone were palpable. The psychologic attitude and emotional stability were normal in 88 of the patients, fair in 4 and poor in 8.

Abnormalities other than genitourinary. One patient had a congenitally dislocated hip and malformed foot arm and ribs, 1 had spina bifida occulta, 1 had a left hemivertebra, 1 had a rudimentary first rib and 1 had a cervical spina bifida and a pelvic kidney. One patient had excessive hair on her chin, hypertension and was obese, but was not considered to have Cushing's syndrome. One patient had sacralization of the fifth lumbar vertebra.

Urologic findings. Forty-one patients underwent a urologic examination consisting of an excretory urogram and, when indicated, a retrograde pyelogram and cystoscopic examination. Twenty patients had a normal urinary tract. Twenty-one patients were found to have abnormalities of the urinary tract, of whom 7 had pelvic kidneys, 5 had solitary kidneys, 4 had a duplicated ureter or renal pelvis, 2 had pyelo-ureterectasis, 1 had a malfunctioning kidney, 1 had a solitary fused kidney and 1 had had nephrectomy on the right for unstated reasons. Ten patients had abnormalities on the right side, and 11 patients had abnormalities on the left side.

Surgical findings. Twenty-six patients underwent pelvic operations which permitted the visualization of the pelvic organs. Of these, 4 patients had anatomically normal tubes, ovaries and uterus, 3 had hematosalpinx, 3 had endometriosis and 10 had normal tubes and ovaries but a malformed uterus (6 infantile uteri, 2 bicornate uteri, 1 unicornate uterus, and 1 instance of cervical atresia with bilateral hematosalpinx). Five patients had normal tubes and ovaries but no uterus. One patient who had no tubes, ovaries, or uterus had vicarious menses through the lungs and rectum.

Ten additional patients underwent inguinal herniorrhaphy. In 7 of these patients the hernial sac contained an ovary. In 1 patient the hernial sac contained a testis and in another it contained an ovotestis and epididymis (proved microscopically). The contents of one hernial sac was not stated.

Twenty-four patients had previously undergone minor vaginal plastic procedures consisting chiefly of hymenotomy. One patient had undergone a Graves procedure and another a Falls procedure for congenital absence of the vagina before coming to the clinic.

RESULTS BY MODE OF TREATMENT

McIndoe procedure Of the 100 patients who were treated surgically for congenital absence of the vagina, 70 underwent McIndoe operations with a Thiersch graft and an inlying mold. All but 15 of the 66 patients traced had obtained excellent results. The average time which had elapsed between the operation and the follow up for the group of 100 patients was more than 4 years. One of the patients in whom eventually excellent results were obtained required two split-skin grafts and then a tertiary graft of fetal membrane. Another patient required a regraft after the primary graft sloughed out during an attack of acute exfoliating dermatitis. Six patients had excellent results but there was some tendency to contracture if the mold was left out and they were unmarried or if the patient's husband was overseas in service and there was no intercourse. One patient who previously had undergone a Graves procedure which resulted in a rectovaginal fistula obtained an excellent result after a secondary McIndoe operation.

Ten patients obtained only satisfactory results, but usually this was because the mold was left out after 6 months when the patients were still single or the mold was used only occasionally between intercourse and some shrinkage occurred and also because there was some contracture as a result of the failure of granulations to epithelize. However 7 of this group who were married reported satisfactory sexual relations.

The results in 5 cases were unsatisfactory. In 1 instance the local physician left the mold out to treat granulations in the vault. In another case a rectovaginal fistula developed colostomy was done and later the rectovaginal fistula was repaired but the second attempt at correction by use of the McIndoe operation resulted in failure. One patient required a secondary Baldwin operation because the obturators were not worn long enough.

Simple reconstruction Fourteen patients were treated by this method in which the obturator is worn after the creation of an artificial space, but grafting is not done. All have had excellent results.

In 1 of these cases Ferris reconstructed the vagina of a 15 year old girl. The patient men-

struated regularly after treatment. In the cases in which biopsy was performed a month or more after the operation squamous epithelium was growing and in 1 case in which immediate biopsy was done a similar result was found.

Baldwin procedure Fourteen patients underwent Baldwin operation in which the ileum was used to create an artificial vagina. Three patients obtained excellent results although one of these patients later needed a repair for prolapse of the bowel and another had undergone a preliminary unsatisfactory attempt at reconstruction by use of the McIndoe method. Five patients obtained satisfactory results but complained of a profuse irritating vaginal discharge which in 1 case required the use of 4 or 5 sanitary napkins a day. Another patient had intestinal obstruction and a fecal fistula 2 years after the operation and 1 reported some vaginal contracture. Four patients died in the hospital of peritonitis or intestinal obstruction. The average length of time between operation and follow up was more than 8 years.

Other procedures One patient underwent a Falls procedure which was apparently satisfactory but this patient could not be traced. Another patient underwent blunt dissection of the rectovesical space and the space was packed with iodoform gauze the result was satisfactory when the patient was last heard from 8 years later.

COMMENT

Reconstruction of an artificial vagina should be attempted only in patients who are married or are contemplating marriage in the very near future or in the occasional case of hematometra, because many of the cases in which the results were unsatisfactory were single women who would not wear the obturator indefinitely and could not have marital relations because of their unmarried status. Also if a patient is unco-operative or has a tendency to be sexually frigid, the reconstruction should not be attempted. The great majority will not require surgical removal of the uterus or its adnexa because these are usually atrophic and asymptomatic. Not infrequently these patients have an associated congenital anomaly of the urinary tract which may require surgical interference namely ectopic pelvic kidneys.

which may be injured during intercourse or infected hydronephrotic kidneys lying in the pelvis. Ureterovaginal fistula may result from anomalous insertion of a ureter.

In 14 cases excellent results have been obtained without grafting. This has been possible because of the inherent ability of the newly formed artificial vagina to epithelize itself. However if there is difficulty in controlling bleeding or in elevating the peritoneum or if the vaginal tract cannot be opened up with ease then a graft should be used. When grafts are not used, epithelium probably arises from the lower segment of the vagina and also from buds of epithelium arising from remnants of the muellerian ducts. Ayre took vaginal smears from an artificial vagina where no graft was used and showed the new lining to be reacting in a cyclic manner to ovarian hormones similar to the way the normal vagina reacts. Whitacre and Wang expressed the thought that the connective tissue elements in this region release a growth stimulating factor especially after trauma. Granulations rarely form in a vagina that is not grafted but if they do they are smaller and are at the sites where bleeding occurred during the original dissection. Marshall has stated that the disadvantages of this simple reconstruction procedure are that a large raw granulating surface is present for 2 to 3 months that secondary hemorrhages occur not infrequently that there is local infection which is not serious and that the procedure must be limited to those patients with a rudimentary vaginal pouch. We have not found these stated disadvantages to be of any consequence. The patients are usually unaware of any discomfort after a brief initial period and there have been only occasional instances of oozing of blood from the vaginal tract. This method can be employed just as easily on the patients without a rudimentary vaginal pouch as on those with a rudimentary dimple.

Thiersch grafts produce excellent results if the take is complete and the mold is worn long enough however occasionally one or more areas are devoid of skin and it is usually necessary to regraft them. McIndoe pointed out that the contraction phase of a canal lined by a Thiersch graft lasts 3 to 6 months or longer

and that removal of the mold before this time has elapsed will result in stricture. This principle applies also to those patients who have not had a graft and the continuous presence of the obturator for 6 months or more is essential.

When a Thiersch graft is used over the mold as has been popularized by McIndoe, the results are usually very satisfactory but it is a more difficult procedure. We have found a greater tendency toward formation of granulation tissue and some areas will need regrafting. This may result in more contractions than when no graft is used. Our series included 70 cases in which the McIndoe procedure was used.

The attempt at reconstruction of an artificial vagina according to the McIndoe principle should not be made if the patient is single and does not intend to be married in the near future or if she is unco-operative, because the mold must be worn for months. Most poor results are due to too early removal of the mold. The lucite mold we use is nonirritating and probably could be worn for years without any deleterious effects. Also the mold should be worn until the perivaginal and perirectal cellulitis has subsided the contractile phase has passed and the entire tract has been epithelized.

When the Baldwin procedure is utilized the mortality is high (28.6 per cent in our series) and the percentage of good results is low. Many of these patients complain bitterly of the vaginal discharge. It is a more difficult operation with greater morbidity and infection. The Schubert rectal transplant method results in a mortality as high as 12 per cent. Also there is danger of infection there is often damage to the sphincter and a considerable portion of the coccyx is removed and frequently an intestinal fistula develops (27).

Operations in which pedicle grafts are used necessitate longer hospitalization and multiple stages. They are more difficult of performance than is simple reconstruction and they have a higher morbidity. Also hair may grow on the inverted flaps. If sloughing occurs, the operation cannot be repeated easily and there is undesirable distortion and mutilation of the vulva (11).

ceral metastasis but only spread to the skin was evident. Thus, there are only 4 cases in which proved metastatic lesions definitely occurred in the viscera and only one in which cutaneous spread was noted. Bereston and Ney concluded that the rarity of metastasis may be explained by the low grade of malignancy and by the possibility that some of the reported cases may have been instances of pseudo-epitheliomatous hyperplasia rather than true malignant neoplasia.

Regarding the subject of the development of carcinoma in fistula in ano Ewing and others had quoted Kraske as follows: "There is no satisfactory evidence that cancer develops in tissues altered by hemorrhoids, fistulae or cicatrices." Since this statement was made, there has been much discussion pro and con. Pennington pointed out in 1923 that fistulas had been known to exist for 35 to 46 years without the occurrence of malignant changes. However, he remarked that epitheliomas occasionally are found a short distance up the rectum where they are supposed to arise from old fistulous openings and similar foci of chronic disease.

Lockhart Mummery and Dukes agreed that occasionally carcinoma occurs in fistulous tracts and reported 2 cases in which carcinoma arose in the primary opening of a chronic fistula in ano.

Rosser in 1931 reported 7 cases in which carcinoma developed in anal fistulas. One patient had been operated on for a fistula and an adjacent polyp 1 year before and the latter lesion recurred. Another patient had small warty growths of squamous-cell epithelioma at the external opening. In the 5 other cases adenocarcinomatous tissue was found invading the fistulous tracts, apparently originating at the primary opening but without tumor formation at this point except in 1 case.

In 1945 David stated that he had seen 5 instances in which carcinoma developed in long-standing fistulous tracts around the rectum. In 1 case the lesion was a basal-cell carcinoma and in the others it was an epithelioma, neither of which is a type that corresponds to what usually is seen in malignant disease of the rectum. The fistulas in 3 of these cases developed in long-standing lesions

of lymphogranuloma inguinale involving the rectum.

A rather extensive review of the literature reveals little information on the subject of the occurrence of epitheliomatous changes in chronic empyemic sinuses. Sauerbrach and O'Shaughnessy did not even make any reference to the occurrence of malignant changes in a chronic sinus when they discussed the complications of chronic empyema. Only one reference was found in the literature and this was simply a case report by Schmid who concluded that carcinomatous changes in fistulas in general, form rare complications in chronic, purulent processes. In his particular case, pneumonia with effusion developed in 1916 and this was treated by thoracotomy; malignant changes were noted in the persistent sinus in 1935 and the patient died within several months, in spite of the use of roentgen and radium therapy.

MATERIALS AND METHODS

This is a review of all those cases encountered at the Mayo Clinic in which malignant changes had taken place in chronic, cutaneous sinuses and fistulas, particular emphasis being placed on cases of chronic osteomyelitic sinuses in which malignant changes occurred and in which metastasis was a complicating factor. Nine such cases are reported along with 3 cases of fistula in ano and 1 case of empyemic sinus from the pleural space.

Blocks of tissue were obtained from the new growths, the infected bone and the adjacent lymph nodes when they were available. These blocks were placed in bottles of 10 per cent solution of formalin. The soft parts were sectioned by the freezing method and were stained with hematoxylin and eosin. The blocks of bone were first decalcified with 5 per cent solution of nitric acid. The stained sections were examined microscopically in order to determine the grade of malignancy and malignant tissue occurring in chronic osteomyelitic sinuses was examined carefully to rule out the possibility of pseudo-epitheliomatous hyperplasia. The nodes were examined for evidence of metastasis and the sections made of the "inflammatory" bone were examined for evidence of tuberculosis.

CLINICAL FEATURES

The files of the Mayo Clinic were productive of 9 cases in which malignant changes occurred in osteomyelitic sinuses (0.23 per cent of approximately 4,000 cases) and 3 in which fistula in ano underwent this change (0.1 per cent of 3,000 cases). In addition 1 empyemic sinus was the site of a similar complication (0.07 per cent of 1,500 cases). These 13 cases serve as the basis for the present study. There were 11 men and 2 women. The duration of the inflammatory tract was 48 years as a maximum and 2 years as a minimum with an average of 26.7 years. The lesion was located in the tibia in 6 cases and in the femur, shoulder, hand and pleural space in 1 case each. Three lesions were fistula in ano.

Signs and symptoms. Osteomyelitic group.—The presence of a new growth was obvious in the sinus in 7 of the 9 cases and 6 patients had observed a recent increase in foul smelling discharge. In 1 case some bloody drainage developed. In only 3 cases was pain a prominent symptom. Enlarged regional lymph nodes were present at examination in 7 of 9 cases and the nodes became invaded later in 2 instances. There was no evidence of tuberculous involvement of the bone. The serologic reaction for syphilis was positive in 1 case. Roentgenograms were interpreted as revealing chronic osteomyelitis and in 1 case the following notation was added: "There is irregular destruction of bone which could be secondary to contiguous malignancy." A pathologic fracture was noticed in 2 instances.

Fistula in ano group.—The chief complaint was persistent drainage. In 1 case the discharge was hemorrhagic and in 1 there was a foul odor. Proctoscopic examination revealed no primary neoplasm in the rectum. In 2 cases an indurated area had been noted 4 and 7 months respectively previously in the tract. Bacteriologic studies in 1 case revealed neither tubercle bacilli nor *Actinomyces*. Flocculation tests gave negative results. The sedimentation rate in 1 case was 59 millimeters in 1 hour (Westergren method). In 1 case two biopsies of deep-lying tissue were necessary before malignant tissue was noted which illustrates the fact that misleading information may be obtained from superficial examination.

Empyemic group.—There was only 1 case in this group. Twenty three years previously the patient with empyema underwent resection of the ribs for pleural effusion and foul drainage persisted. Three years before admission dull steady pain had been noticed. Three months prior to admission blood had appeared in the discharge and dyspnea on exertion had developed. Examination of the sputum and of the discharge from the sinus had failed to reveal tubercle bacilli or sulfur granules. The sedimentation rate was 83 millimeters, the leucocyte count was 8,500 per cubic millimeter of blood, the erythrocyte count was 4,200,000 per cubic millimeter and the hemoglobin measured 14 grams per 100 cubic centimeters of blood. Roentgenograms of the thorax had revealed only thickened pleura.

PATHOLOGIC FEATURES

Osteomyelitic group.—In 2 of the 9 cases (22.2 per cent) metastasis to the regional lymph nodes occurred as a complication.

In all of the 5 sections of bone available for study evidence of nonspecific inflammation was found.

All the lesions were characteristic of squamous cell epithelioma and for the most part were of a low grade (Broders' method). 3 were graded 1, 5 were graded 2 and 1 was graded 3. Of the 2 lesions which metastasized 1 was graded 2 and the other was graded 3.

One lesion was originally reported as a grade 3 epithelioma and fibrosarcoma but a review of other sections revealed that it was actually an epithelioma simulating a fibrosarcoma (Fig. 1). This is not a new concept because it has been observed in so called sarcoma of the thyroid and in oat cell tumor of the lung.

In 1 case the biopsy was reported as revealing epithelial hyperplasia and the lesion was excised locally but in less than a year it had recurred and specimens from the amputated leg were characteristic of grade 1 epithelioma.

CASE 1. A 57 year old man had had a draining sinus in the upper third of the right tibia for 48 years and 1 year before admission he had noted a small nodule at the side of the tract. Only a biopsy was done which revealed much keratin and some epithelial pearls. In addition there were pale cells with hyperchromatic nuclei and mitotic figures were

b

c

Fig. Grade 3 squamous cell epithelioma simulating fibrosarcoma. This lesion occurred in chronic osteomyelitic focus in the right foot. a, $\times 95$. b, Note mitotic figures ($\times 500$). c, Metastatic lesion in inguinal lymph node ($\times 35$).

quite rare. The lesion was interpreted as a low grade 2 squamous cell epithelioma but the patient left without undergoing further surgical procedures.

CASE 2. A 61 year old man had had a chronic draining sinus in the right medial malleolus resulting from osteomyelitis at the age of 14 years. For a year before admission there had been increased swelling and pain. A cauliflower-like mass measuring 10 by 7 by 1.6 centimeters was present. Microscopically epithelial hyperplasia was present and there were occasional mitotic figures which were definitely some distance superficial to the basement membrane. Both epithelial pearls and intercellular bridges were present. Many plasma cells and fibroblast were observed. The lesion was classified as a grade 1 epithelioma.

CASE 3. A 50 year old man had had a draining sinus in the lower part of the right leg for 15 years. Four months before admission he had observed some little growths at the site of ulceration, and on examination at the clinic a cauliflower-like growth measuring 11 by 8 by 0.5 centimeters was noted. Microscopically no pearls were seen but there were cords and clumps of pale-staining squamous cells that penetrated irregularly into the surrounding tis-

sue. Nuclei were hyperchromatic and of variable size. The lesion was classified as a grade 2 epithelioma.

CASE 4. A 45 year old man had had the first symptoms of osteomyelitis of the lower part of the right femur at the age of 8 years. At age 35 there were pain and swelling in the right hip and pus was aspirated since then there had been continuous purulent drainage. On examination a mass around the ostium of the sinus at the upper posterior aspect of the right thigh measuring 6 by 5 by 2 centimeters was observed. Microscopically the squamous epithelial cells were large, and hyperchromatic and occasional mitotic figures were seen. Only minimal pearl formation was noted. Many polymorphonuclear leucocytes, fibroblasts, erythrocytes, and plasma cells were present. The lesion was graded 2.

CASE 5. A 57 year old man had had a draining sinus in the right leg for 33 years. Four years before the first admission a sequestrum had been excised. In October 1941 examination revealed a granulating mass 3 by 3 centimeters and biopsy of superficial tissue disclosed what was reported as epithelial hyperplasia, however the excised specimen removed at operation contained numerous epithelial pearls

and some pearls were observed in a nearby lymph follicle. Occasional mitotic figures were seen. On July 24, 1912, an amputation was performed at the juncture of the lower and middle thirds of the right femur. The papillomatous lesion extended 1.5 centimeters above the surface of the skin; it was 10 centimeters long by 2 centimeters wide. Microscopically, numerous cords and strands of squamous cells in which there were occasional mitotic figures were observed. Pearls were numerous, and often there was peripheral palisading of the epithelial cells. The lesion appeared to be a grade 1 epidermoid carcinoma.

This case illustrates the misleading information which may be obtained from a biopsy of superficial tissue.

The following case is of interest because carcinoma of the sinus was complicated by the occurrence of metastasis.

CASE 6. In 1917 the patient had received an extensive crushing and burn injury to the right hand. Since then the skin had broken down and had healed on numerous occasions. In March 1938 the hand was explored and a keloid was excised from the dorsum. In November 1938 roentgenograms revealed osteomyelitis of the metacarpals of the right hand and at that time some sequestra were removed. Since then there had been constant drainage. When the patient was first seen at the clinic in March 1939, examination of the dorsum of the right hand revealed an ulcer 3 inches (7.6 cm.) in circumference with dirty necrotic bone in its base. At that time the third, fourth and fifth fingers and the corresponding metacarpals were amputated. Microscopically, pearls were present as were pale cells with pathologic mitotic figures. Some of the cells contained vacuoles which gave them a pagetoid appearance. There was invasion of bone and many polymorphonuclear leukocytes, giant cells, plasma cells and mast cells were seen. This lesion was classified as a grade 2 epithelioma. The patient was admitted for the second time on April 22, 1942, because of considerable pain in the right axilla. Physical examination revealed a mass the size of an egg in the axilla and this was incompletely excised because of the extensive invasion. Microscopically the regional lymph nodes showed polygonal cells with pale cytoplasm and large hyperchromatic nuclei (Fig. 2). Very few mitotic figures were seen and fibrous tissue had replaced most of the lymphoid elements. The lesion was interpreted as a grade 2 epithelioma.

CASE 7. A 58 year old woman had had drainage, off and on, from a sinus located at the lower third of the right tibia for 48 years. Three months before admission a "painless knot" began to grow above the right ankle. On examination the right leg exhibited a healed, scarred sinus on the middle of the anterior surface. Over the anterior surface of the lower third there was a cauliflower like mass measuring 7 by 5 by 2.5 centimeters. Microscopically there were

Fig. 2. Axillary lymph node metastasis showing grade 2 squamous cell epithelioma. Primary was grade 2 squamous cell epithelioma developing in chronic osteomyelitis of the right hand ($\times 90$).

huge epithelial pearls—many containing cells with intercellular bridges. Peripheral palisading was prominent and in addition there were cords, plugs and strands of epithelial cells. The lesion was considered to be a grade 1 squamous cell epithelioma.

CASE 8. A 47 year old man had undergone a left glenohumeral disarticulation at the age of 17 years after his arm had been caught in a machine. Three years before admission the scar over the amputation site had broken down, discharging clear serum that gradually became purulent and foul-smelling. For 7 months a reddish growth measuring 6 by 4 by 1 centimeter had been noted. Excision of the growth, the remaining portion of the scapula and a portion of clavicle was carried out. Microscopically, mitotic figures were noted in the pale epithelial cells which were arranged in typical pearl formation. The lesion was interpreted as a grade 2 epithelioma.

CASE 9. A 37 year old man had had osteomyelitis with drainage for 33 years. On April 10, 1933, when he reported to the clinic, he stated that since the last visit in 1927 the painful leg had improved but the sinus continued to drain. Two months before admission soreness developed in the ankle and 10 days before hemorrhage occurred from the sinus. On August 22, 1933, the right leg was amputated at the juncture of middle and upper thirds. Four months later an inguinal lymph node was excised. The specimen consisted of the right foot, the lower two thirds of the leg and an excised lymph node. A sinus was located just superior to the medial malleolus and this led down into the marrow of the tibia where there was a cavity which measured 7 by 6 centimeters and the wall of which consisted of firm rubbery tissue 3 centimeters in thickness. Certain sections showed many large squamous cells with hyperchromatic nuclei and numerous mitotic figures and an occasional well developed epithelial pearl was seen (Fig. 3a). Other sections showed large spindle cells with pale cytoplasm and pathologic mitotic figures (Fig. 3b). Many polymorphonuclear leukocytes and

quite rare. The lesion was interpreted as a low grade 2 squamous cell epithelioma but the patient left without undergoing further surgical procedures.

CASE 2. A 61 year old man had had a chronic draining sinus in the right medial malleolus resulting from osteomyelitis at the age of 14 years. For a year before admission there had been increased swelling and pain. A cauliflower-like mass measuring to by 7 by 1.6 centimeters was present. Microscopic

ly epithelial hyperplasia was present and there were occasional mitotic figures which were definitely some distance superficial to the basement membrane. Both epithelial pearls and intercellular bridges were present. Many plasma cells and fibroblasts were observed. The lesion was classified as a grade 1 epithelioma.

CASE 3. A 50 year old man had had a draining sinus in the lower part of the right leg for 10 years. Four months before admission he had observed some little growths at the site of ulceration and on examination at the clinic a cauliflower-like growth measuring 12 by 8 by 0.5 centimeters was noted. Microscopically no pearls were seen but there were cords and clumps of pale-staining squamous cells that penetrated irregularly into the surrounding tis-

sue. Nuclei were hyperchromatic and of variable size. The lesion was classified as a grade 2 epithelioma.

CASE 4. A 45 year old man had had the first symptoms of osteomyelitis of the lower part of the right femur at the age of 8 years. At age 15 there were pain and swelling in the right hip and pus was aspirated since then there had been continuous parent drainage. On examination a mass around the osium of the sinus at the upper posterior aspect of the right thigh measuring 6 by 5 by 2 centimeters was observed. Microscopically the squamous epithelial cells were large, and hyperchromatic nuclei and occasional mitotic figures were seen. Only minimal pearl formation was noted. Many polymorphonuclear leucocytes, fibroblasts, erythrocytes, and plasma cells were present. The lesion was graded 2.

CASE 5. A 57 year old man had had a draining sinus in the right leg for 33 years. Four years before the first admission a sequestrum had been excised. In October 1943 examination revealed a granulating mass 3 by 3 centimeters and biopsy of superficial tissue disclosed what was reported as epithelial hyperplasia; however the excised specimen removed at operation contained numerous epithelial pearls

One patient underwent excision and cautery in September 1921 and died in July 1922. The cause of death was not stated. Radium therapy was apparently without benefit.

Another patient underwent excision of soft tissue and bone from the site of a disarticulation of the left humerus that had been performed 40 years earlier. The patient was given roentgen therapy and 4 years later had had no recurrence.

Two patients underwent excision and curettement one or more times and eventually required amputation. They are both well 4 and 13 years respectively after amputation.

In 1 case (Case 1) in which only a biopsy was done operation was not performed at the clinic. However a letter was sent immediately to the patient's family physician advising that the extremity be amputated because of the malignant nature of the lesion. We have been unable to trace this patient.

Fistula in ano group In Case 10 the cavity of the anal fistulous tract was simply curetted and then packed with iodoform gauze. This was done on February 15, 1922 and on October 21, 1923 the patient died of carcinoma toxis.

In Case 11 the entire right ischio-rectal fossa was laid bare and the right wall of the rectum was exposed for about 3 inches (7.5 cm). Between March 12 and March 20, 1931, 2,343 milligram hours of radium were applied to the region of the sinus and from March 14 through March 18, 1931, 4,200 milligram hours of radium were given to the left groin and 4,186 milligram hours administered to the right groin. From June 12 to June 13, 1931, 4,200 milligram hours were applied again to the right groin. At biopsy on September 11, 1931, tissue from the right ischio-rectal fossa proved to be malignant. Consequently treatment of the lesion with radon needles was carried out as follows: September 12, 1931, 480 milligram hours; December 11, 1931, 782 milligram hours; and March 24, 1932, 336 milligram hours. The patient died on April 12, 1941, from carcinoma of the rectum according to his family physician.

In Case 12 left loop colostomy was performed after biopsy of deep tissues revealed colloid adenocarcinoma grade 1 on October

Fig. 4. Grade 2 squamous cell epithelioma occurring in a chronic empyemic sinus ($\times 65$).

12, 1943. At that time no involvement of the lymph nodes was observed. On November 2, 1943, diathermy was used to remove all the perirectal skin over the growth and the growth itself plus the distal 4 to 5 inches (10 to 12 cm) of the rectum. The patient had received 8 weekly roentgen ray treatments elsewhere preoperatively but the amount was not stated. Postoperatively no more radiation was given. Correspondence on July 15, 1946, indicated that the patient was living and well and had had no recurrence.

Empyemic group The malignant empyemic sinus was treated by radical excision after the removal of two ribs. However it was felt that not all of the neoplastic tissue was excised. When the patient left the hospital 2 weeks after operation he was complaining bitterly of pleural pain and required frequent doses of opiates. He was not heard from subsequently.

COMMENT AND SUMMARY

It has been thought that Cohnheim's theory of chronic irritation accounted for the malignant change occurring in these tracts. However we feel that too much emphasis has been

Fig. 3 Malignant changes occurring in chronic fistula in ano. Section showing grade 3 squamous cell epithelioma.

plasma cells and an occasional foreign body giant cell were noted. Microscopic section of the lymph node showed numerous large pale epithelial cells with hyperchromatic nuclei. Mitotic figures were numerous (Fig. 1c).

Both the primary and metastatic lesions were interpreted as grade 3 squamous cell epithelioma simulating fibrosarcoma.

Fistula in ano group—Of the malignant lesions developing in a fistula 1 was a squamous cell epithelioma and 2 were adenocarcinomas. All 3 were grade 1 lesions. No sinus was identified and the rectal mucosa was normal in each case.

CASE 10—A 49 year old man had had a persistent draining fistula for 22 years. The anal canal and mucosa appeared normal. Examination of the tissue obtained by curettage revealed cords and strands of squamous malignant cells with no pearls (Fig. 3a). Plasma cells and polymorphonuclear leukocytes were numerous. Apocrine glands were noted in the deep tissues. This was classified as a grade 1 squamous cell epithelioma.

CASE 11—Eighteen years before the patient was admitted to the clinic an ischioanal abscess was incised and it continued to drain until 4 years before admission when the fistula healed, but occasionally a small amount of pus appeared from the rectum. Four months before admission pain was noted and a tumor appeared. Microscopic examination of tissue obtained when the right ischioanal fossa was laid bare showed definite acinar formation and there were well differentiated columnar epithelial cells. Plasma cells were numerous but no mucin was visible. The lesion was a grade 1 adenocarcinoma.

CASE 12—A 58 year old man had had a fistula for 6 years with persistent drainage and 6 months before admission a honeycomb region of draining ab-

nuses had appeared. The site of tumefaction measured 6 by 8 centimeters. The growths plus the distal 4 or 5 inches (10 or 12 cm.) of the rectum were excised. Microscopic examination of the tissue disclosed well formed acini containing much mucin, and the lesion was considered to be grade 1 adenocarcinoma (Fig. 3b). The lymph nodes were the site of inflammatory changes.

Empyemic group—There was only 1 case in this group.

CASE 13—A 55 year old man was seen in February 1946 on account of a chronic empyemic sinus which had been draining since 1918 and had followed thoracotomy for a pleural effusion. Three months before admission, blood began to appear in the foul smelling discharge. Microscopic examination of the excised tract and thickened pleura disclosed much hemorrhage and many lymphocytes and there were numerous cords and plugs of epithelial cells. Pearls and intercellular bridges were present and there was a tendency toward peripheral palisading. Occasional mitotic figures were seen. The lesion was a grade 2 epithelioma (Fig. 4).

TREATMENT AND RESULTS

Osteomyelitic group—Three patients were treated by amputation and 1 of these had postoperative therapy with roentgen rays. One of these 3 patients lived 11 years and died from gastric carcinoma, another was alive 21 years postoperatively and the third died from chronic nephritis 14 years after amputation.

One patient underwent partial amputation in March 1939, and in April 1942 metastatic lesions were observed in the axillary nodes. Death occurred in July 1942.

One patient underwent excision and cautery in September 1921 and died in July 1922. The cause of death was not stated. Radium therapy was apparently without benefit.

Another patient underwent excision of soft tissue and bone from the site of a disarticulation of the left humerus that had been performed 40 years earlier. The patient was given roentgen therapy and 4 years later had had no recurrence.

Two patients underwent excision and curettement one or more times and eventually required amputation. They are both well 4 and 13 years respectively after amputation.

In 1 case (Case 1) in which only a biopsy was done operation was not performed at the clinic. However a letter was sent immediately to the patient's family physician advising that the extremity be amputated because of the malignant nature of the lesion. We have been unable to trace this patient.

Fistula in ano group. In Case 10 the cavity of the anal fistulous tract was simply curetted and then packed with iodoform gauze. This was done on February 15 1922 and on October 21 1923 the patient died of carcinoma totis.

In Case 11 the entire right ischiorectal fossa was laid bare and the right wall of the rectum was exposed for about 3 inches (7.5 cm). Between March 12 and March 20 1931 2 343 milligram hours of radium were applied to the region of the sinus and from March 14 through March 18 1931 4 200 milligram hours of radium were given to the left groin and 4 186 milligram hours administered to the right groin. plasma cells and an occasional foreign body giant cell were noted. Microscopic section of the lymph node showed numerous large pale epithelial cells with hyperchromatic nuclei. Mitotic figures were numerous (Fig. 1c).

Both the primary and metastatic lesions were interpreted as grade 3 squamous cell epitheliomas. Infiltrating fibrosarcoma.

Fistula in ano group—Of the malignant lesions developing in a fistula 1 was a squamous cell epithelioma and 2 were adenocarcinomas. All 3 were grade 1 lesions. No sinus was identified and the rectal mucosa was normal in each case.

CASE 10. A 49 year old man had had a persistent draining fistula for 22 years. The anal canal and mucosa appeared normal. Examination of the tissue obtained by curettage revealed cords and strands of squamous malignant cells with no pearls (Fig. 3a). Plasma cells and polymorphonuclear leukocytes were numerous. Apocrine glands were noted in the deep tissues. This was classified as a grade 1 squamous cell epithelioma.

CASE 11. Eighteen years before the patient was admitted at the clinic an ischioanal abscess was incised and it continued to drain until 4 years before admission when the fistula healed but occasionally small amount of pus appeared from the rectum. Four months before admission pain was noted and a tumor appeared. Microscopic examination of the tissue obtained when the right ischiorectal fossa was laid bare showed definite acinar formation and there were well differentiated columnar epithelial cells. Plasma cells were numerous but no mucin was visible. The lesion was a grade 1 adenocarcinoma.

CASE 12. A 58 year old man had had a fistula for 6 years with persistent drainage, and 6 months before admission a honeycomb region of draining si-

nuses had appeared. The site of tumor formation measured 6 by 8 centimeters. The growths plus the distal 4 or 5 inches (10 or 12 cm) of the rectum were excised. Microscopic examination of the tissue disclosed a well formed acini containing much mucin, and the lesion was considered to be a grade 1 adenocarcinoma (Fig. 3b). The lymph nodes were the site of inflammatory changes.

Empyemic group—There was only 1 case in this group.

CASE 13. A 55 year old man was seen in February 1946 on account of a chronic empyemic sinus which had been draining since 1918 and had followed thoracotomy for a pleural effusion. Three months before admission blood began to appear in the foul smelling discharge. Microscopic examination of the excised tract and thickened pleura disclosed much hemorrhage and many lymphocytes and there were numerous cords and plugs of epithelial cells. Pearls and intercellular bridges were present and there was a tendency toward peripheral palisading. Occasional mitotic figures were seen. The lesion was a grade 2 epithelioma (Fig. 4).

TREATMENT AND RESULTS

Osteomyelitic group—Three patients were treated by amputation and 1 of these had postoperative therapy with roentgen rays. One of these 3 patients lived 11 years and died from gastric carcinoma; another was alive 21 years postoperatively and the third died from chronic nephritis 14 years after amputation.

One patient underwent partial amputation in March 1939, and in April 1942 metastatic lesions were observed in the axillary nodes. Death occurred in July 1942.

One patient underwent excision and cautery in September 1921 and died in July 1922. The cause of death was not stated. Radium therapy was apparently without benefit.

Another patient underwent excision of soft tissue and bone from the site of a disarticulation of the left humerus that had been performed 40 years earlier. The patient was given roentgen therapy and 4 years later had had no recurrence.

Two patients underwent excision and curettage one or more times and eventually required amputation. They are both well 4 and 13 years respectively, after amputation.

In 1 case (Case 1) in which only a biopsy was done, operation was not performed at the clinic. However a letter was sent immediately to the patient's family physician advising that the extremity be amputated because of the malignant nature of the lesion. We have been unable to trace this patient.

Fistula in ano group. In Case 10 the cavity of the anal fistulous tract was simply curetted and then packed with iodoform gauze. This was done on February 15 1922 and on October 21 1923 the patient died of carcinoma tonsis.

In Case 11 the entire right ischio-rectal fossa was laid bare and the right wall of the rectum was exposed for about 3 inches (7.5 cm). Between March 12 and March 20 1931 2 343 milligram hours of radium were applied to the region of the sinus and from March 14 through March 18 1931 4 200 milligram hours of radium were given to the left groin and 4 186 milligram hours administered to the right groin. From June 12 to June 13 1931 4 200 milligram hours were applied again to the right groin. At biopsy on September 11 1931 tissue from the right ischio-rectal fossa proved to be malignant. Consequently treatment of the lesion with radon needles was carried out as follows: September 12 1931 480 milligram hours; December 11 1931 782 milligram hours; and March 24 1932 336 milligram hours. The patient died on April 12 1941 from carcinoma of the rectum according to his family physician.

In Case 12 left loop colostomy was performed after biopsy of deep tissues revealed colloid adenocarcinoma grade 1 on October

12 1943. At that time no involvement of the lymph nodes was observed. On November 2 1943 diathermy was used to remove all the perirectal skin over the growth and the growth itself plus the distal 4 to 5 inches (10 to 12 cm) of the rectum. The patient had received 8 weekly roentgen ray treatments elsewhere preoperatively but the amount was not stated. Postoperatively no more radiation was given. Correspondence on July 15 1946, indicated that the patient was living and well and had had no recurrence.

Empyemic group. The malignant empyemic sinus was treated by radical excision after the removal of two ribs. However it was felt that not all of the neoplastic tissue was excised. When the patient left the hospital 2 weeks after operation he was complaining bitterly of pleural pain and required frequent doses of opiates. He was not heard from subsequently.

COMMENT AND SUMMARY

It has been thought that Cohnheim's theory of chronic irritation accounted for the malignant change occurring in these tracts. However we feel that too much emphasis has been

placed on the factor of chronic irritation and the basis for our attitude is the occurrence of a low incidence of malignant change in our series—0.23 per cent in the cases of osteomyelitis, 0.1 per cent in the cases of fistula in ano and 0.07 per cent in the cases of chronic empyema. Millgram observed a patient with osteomyelitis for 62 years without finding any evidence of neoplastic change and Pennington reported that DePage had occasion to treat a benign fistula in ano that had existed for 38 years. Roklitsky examined the third specimen of squamous cell epithelioma developing in an osteomyelitic tract (Ditttrich's case) and observed that epithelial cells were growing down the sinus deep into the cavity of the bone. Cone, Schindler, Kaufmann and Brunschwig agreed that there is not much dispute that epitheliomas form from preformed epithelium and that a fistula from a diseased bone which has become epithelized may undergo malignant change.

White and Weidman stated that mitotic figures are seen in simple inflammation and regeneration and that the diagnosis of carcinoma in chronic ulcers is unjustifiable except when infiltration extends to the level of the sweat glands or farther. Consequently they stated that many of the so called carcinomas that develop in a sinus of chronic osteomyelitis are not really malignant but are examples of pseudoepitheliomatous hyperplasia and consequently the incidence of metastasis in such cases is low. However Broders concluded that the day has passed when epithelium can be considered noncancerous, or at most only precancerous because it is within the confines of the basement membrane and conversely it is not carcinomatous simply because it has penetrated the basement membrane. The character of the individual cell is the important factor.

Again it must be emphasized that the two conditions, namely hyperplasia and neoplasia, may coexist. The biopsy in Case 5 revealed epithelial hyperplasia but examination of blocks from the excised specimen revealed epithelial pearls with occasional mitotic figures. Nine months later the sinus had persisted and another irregular raised tumor measuring 10 by 3 by 1.5 centimeters had appeared sections

of which showed cords and strands of squamous cells with occasional mitotic figures. The presence of pearls and intercellular bridges was noted and in addition there was a tendency to peripheral palisading. At that time amputation of the patient's right leg was carried out. Also in Case 12 the first biopsy was reported as disclosing epithelial hyperplasia with keratosis but microscopic examination of sections from the excised specimen revealed well formed acini with much mucus, and the lesion was diagnosed grade 1 adenocarcinoma. It is granted that epithelial hyperplasia occurring in a chronic osteomyelitic sinus may be misinterpreted as a manifestation of epithelioma with the result that a needless amputation may be performed. However we think that when the biopsy of tissue from a chronic draining sinus or fistula discloses epithelial hyperplasia a wider excision of the sinus should be performed and blocks should be studied carefully for evidence of malignant changes.

Hellner, Benedict and Niebauer pointed out the roentgenologic findings which would make one suspect that malignant changes are taking place around osteomyelitic cavities. This change consists of areas of rarefaction observed in the bone surrounding the cavities. Such a change occurred in our Case 9 (Fig. 5).

Devars in his review stated that of the 39 cases of osteomyelitis in which malignant changes occurred metastasis to the lymph nodes was noted in 50 per cent and the prognosis was especially grave. No photomicrographs were presented as evidence of metastasis. In the 12 cases reported by Benedict no metastasis was observed and he concluded that the prognosis was favorable owing to the fact that the neoplasm grew slowly and usually was of a low order of malignancy. Up to the year 1941 there were only 7 cases of epithelioma occurring in an osteomyelitic sinus in which proved metastasis occurred and Berenson and Ney added 2 more cases to the literature. In our series of 9 cases of osteomyelitis in which carcinoma developed metastasis occurred in 2 cases (22.2 per cent). One of these patients was living 13 years after amputation of a leg.

In 6 of our 9 cases (66.7 per cent) there were enlarged lymph nodes at the time of operation.

In none of these was biopsy performed but 1 patient died a year later. Two of the 3 patients without palpable nodes eventually had metastasis to the nodes proved by biopsy. Accordingly we propose that even in the face of negative results on biopsy, roentgen ray treatment should be given over the regional nodes and even a prophylactic dissection of these nodes might be considered.

The neoplasms which occur in chronic fistula in ano may be of a squamous cell or basal cell type or glandular in structure. Usually those arising near the anus are adenocarcinomas but owing to the presence of both squamous and columnar epithelium at the dentate line the growth may be of an epitheliomatous nature also. This view is strongly advocated by Rosser (23). Hermann as well as Tucker and Hellwig have demonstrated well developed tubular structures which run from the crypts of Morgagni into the submucosa and sometimes into the internal sphincter. In 1945 Kratzer stated that these ducts could provide a pathway for infecting organisms to penetrate the muscle surrounding the anal canal and thus could produce abscesses with subsequent fistulas.

We examined 5 normal anal rings from specimens removed in combined abdominoperineal resection and demonstrated the presence of erratic glands in the depths of the crypts. We agree with Kratzer that when there is cryptitis these glands may provide a pathway for infecting organisms to penetrate the sphincter as a result of which an ischioanal abscess and subsequent fistula may develop. Also we agree with Rosser (23) that malignant changes may occur in either of the two types of epithelium present as adenocarcinoma occurred in 2 squamous cell epithelioma in 1 of our cases.

The epithelium which became malignant in our case of chronic empyema probably was derived from an inward growth of the surface epithelium just as the surface epithelium grows down to line the chronic osteomyelitic sinus. Since there is no good reason to support the idea that the pleural endothelium may undergo metaplasia we subscribe to the theory that epithelium came from epithelium in this case because at operation the old sinus was observed to be completely epithelialized.

Fig. 5. Grade 3 squamous cell epithelioma invading an osteomyelitic cavity. This demonstrates the small areas of rarefaction in sclerotic bone surrounding the cavities which Hellner said suggest malignant invasion.

CONCLUSIONS

1. Malignant changes in a chronic osteomyelitic sinus should be suspected when a growth appears in the sinus, the discharge becomes more foul smelling or hemorrhagic, a painful swelling appears and when the roentgenogram reveals a pathologic fracture or areas of rarefaction surrounding the osteomyelitic cavity. There were 9 such cases in our series.

2. In our series there were 2 cases in which metastasis occurred from a malignant lesion in a chronic osteomyelitic sinus; these added to the 9 cases reported in the literature make 11 cases in which distant spread occurred.

3. It is proposed that the regional lymph nodes be treated with roentgen rays and that even a prophylactic dissection of these nodes be considered.

4. The transitional epithelium from the erratic glands of the anal crypts probably in

vades the fistula in ano tracts and this may account for the fact that acini are located in some of the fistulous tracts which have shown malignant change. Three such cases are presented in our series.

5 Malignant disease occurring in a chronic empyemic sinus is a surgical rarity. There was 1 case in our series.

6 When the biopsy reveals epithelial hyperplasia the sinus or fistula should be excised and blocks studied for evidence of malignant changes. If neoplastic tissue is found amputation should be done in cases of osteomyelitis and rather radical excision should be done for fistula in ano and empyemic sinuses.

THE EFFECT OF INTRAVENOUS GLUCOSE AND AMINO ACIDS ON GLYCOSURIA AND URINARY OUTPUT IN HUMANS

CHARLES E. LOCKHART M.D. Columbia, Missouri and ROBERT ELMAN M.D. F.A.C.S.
St. Louis, Missouri

THE proper rate at which intravenous solutions of glucose should be injected without producing glycosuria and an unwanted diuresis is of obvious clinical importance. This was studied in normal adult individuals given single 1 liter intravenous injections of various glucose solutions under standard conditions but at varying controlled rates. The findings reveal that a slower rate of administration than is ordinarily used should be employed if these undesirable factors are to be eliminated. In addition the experiments indicate that amino acids either as such or as hydrolyzed protein when given in combination with glucose solutions tend to increase the rate of utilization of glucose. This effect was evidenced by the lessened degrees of glycosuria and the lower blood sugar curves which were observed when glucose was administered simultaneously with amino acid solutions than when glucose alone was given at the same rates.

Since 1900 various workers have sought to determine the rate of utilization of glucose in humans and experimental animals in both normal and abnormal states. It has long been recognized that an accurate glucose tolerance can be determined only by introducing the glucose directly into the blood stream, thereby eliminating the variable factors of absorption from the alimentary tract. In 1905 Blumenthal first studied the utilization of glucose by the tissues after intravenous injection. Using normal rabbits he injected varying single doses at 15 minute intervals and observed a retention between 0.15 and 0.32 gram

glucose per kilogram body weight every 15 minutes (0.6 to 1.2 gm per kgm per hour) without glycosuria. Using the same intermittent injection methods, Comessatti in 1906 demonstrated that the rate of utilization was slightly increased in rabbits during and after exercise.

Continuous intravenous injection was first introduced by Woodyatt, Sansum and Wilder in 1915 in order to arrive at more accurate figures than could be obtained by the intermittent method. They administered solutions of 18 per cent glucose to normal dogs, rabbits, and adult humans (4 laboratory workers) continuously over periods up to 4 hours in humans. 12 hours in dogs using a motor-driven pump to aid in regulating different injection rates. On the basis of their observations they stated that glycosuria consistently appeared at injection rates above 0.9 gram glucose per kilogram body weight per hour, and did not appear at rates below 0.8 gram per kilogram per hour. No species or sex differences were observed. On the basis of this report the figure 0.85 gram per kilogram per hour has been looked upon as being the normal rate of utilization of glucose during intravenous injection in humans and has remained without further experimental verification for 32 years. Sansum and Wilder reported observations in 1917 on glucose utilization in abnormal states. They stated that glucose tolerance was decreased in patients with hyperthyroidism, chronic pancreatitis, mild diabetes, acromegaly and diabetes insipidus. No lowering of tolerance was seen in patients with alcoholic cirrhosis of the liver.

Postoperative utilization of intravenous glucose was studied by Fantus in 1936. In a series of patients receiving over 200 grams of glucose per day glycosuria was observed in

TABLE I.—EFFECT OF AMINO ACIDS ON GLYCOSURIA FOLLOWING INTRAVENOUS GLUCOSE

Solution	Rate of Injection	N. Injections	No. patients showing glycosuria
Glucose alone	Less than 1 gm./kgm./hr.	6	
Glucose and amino acids		6	
Glucose alone	More than 1 gm./kgm./hr.	66	69*
Glucose and amino acids		24	†

*Range of glycosuria, 1 to 6 grams

†Range of glycosuria, trace to 34 grams

over half of the subjects. The rate of injection of the glucose solutions, however, was not regulated. In 1938 Winslow reported another study of glycosuria in postoperative patients who were given intravenous glucose at various controlled rates. This author found a greater tendency for glycosuria to appear during the first 5 days after operation than at any other time and at slower rates of administration than had been observed by Wood yatt in normal animals and humans. For example when 10 per cent glucose was injected at rates of .4 to 8 gram per kilogram per hour during these postoperative days glycosuria would appear in amounts up to 5 per cent of the glucose given. When 5 per cent glucose was used glycosuria was seen to occur in rates as low as 0.35 gram per kilogram per hour however even when a total of 150 grams was administered at this rate usually less than 2.5 grams would be lost through glycosuria.

MATERIALS AND METHODS

One hundred and four timed and controlled 1 liter injections of glucose solutions were given intravenously to 32 selected adult humans. These subjects were patients in the general surgical wards of the two hospitals they were considered normal in that all were either awaiting plastic or other elective procedures, and consented to postpone their day of operation in order to take part in this study or they had had their operation at least 8 to 10 days previously and were ambulatory and about to be discharged from the hospital. All subjects exhibited normal urinalyses, normal blood glucose and nonprotein nitrogen levels and were in a normal state of nutrition on

regular diets. Their average weight was 69 kilograms. Each subject was weighed the evening before the experiment and the rate of administration of glucose was calculated upon this basis. The glucose solutions employed were those commonly used in hospital wards, and were administered intravenously in the usual amount (1 liter) at various rates, ranging from 0.35 to 3.1 grams per kilogram per hour. The presence and degree of glycosuria resulting from each injection and the degree of associated diuresis were measured in each case. The following solutions were utilized (1) 5 per cent glucose in water (2) 5 per cent glucose in isotonic saline (3) 10 per cent glucose in water (4) 10 per cent glucose in isotonic saline (5) 5 per cent amigen in 5 per cent glucose (6) 5 per cent amigen in 10 per cent glucose (7) 5 per cent pure amino acids in 5 per cent glucose (8) 15 per cent glucose in water (9) 15 per cent glucose in 5 per cent amigen (10) 15 per cent glucose in 5 per cent pure amino acids (11) isotonic saline solution. Nothing was given orally after the midnight prior to the morning's infusion. The patient voided completely or was catheterized just prior to beginning the intravenous injection. All urine was then saved during the next 4 hour period including the time consumed by the intravenous infusion. At the end of the 4 hour period the subject voided completely or was catheterized. Each subject was kept supine in bed the infusion was set and kept at a steady rate by means of an ordinary intravenous administration set with a screw clamp and was watched during the entire period of administration to insure its constant unchanging rate of drip. No food or drink was allowed during the 4 hour period. For the first 30 injections 24 hour urine specimens were also saved and examined but in no case was glucose found to be excreted after 4 hours, so only 4 hour specimens were examined thereafter. The amount of glucose excreted was determined by the quantitative urinary glucose method of Somogyi. Traces less than 0.1 per cent were noted by Benedict's qualitative test.

RESULTS

The relation between glycosuria and the rate of injection of glucose is shown in the next

Fig 1 Glycosuria following intravenous glucose. Each point represents 1 experiment. The horizontal broken line represents the rate set by Woodyatt before which glycosuria occurred. Note only at a rate much lower than this (solid horizontal line) did glycosuria occur in these observations (with 1 exception). Note also a tendency for an increase in the amount of glycosuria with increasing rates of injection.

ter graph in Figure 1. From this it will be seen that when glucose was injected at rates less than 0.5 gram per kilogram per hour no glycosuria was produced except in 1 instance whereas at the rates of 0.5 gram per kilogram per hour and above, glycosuria appeared in all but 6 cases. The degree of glycosuria varied considerably among patients and also in single patients when different solutions were given at the same rates. However the rate at and above which glycosuria appeared was constant (0.5 gm./kgm./hr.) rather than at the figure 0.85 as might have been expected in normal humans as a result of Woodyatt's observations. The administration of intravenous glucose at the rate of 0.5 gram per kilogram per hour would mean in practical usage giving 1 liter of 5 per cent glucose to an average (70 kgm.) person at a steady rate over a period of 1 hour and 25 minutes. One liter of 10 per cent glucose would require a period of 2 hours and 50 minutes if glycosuria with associated diuretic effect is to be avoided. The

findings also suggest a tendency for the amount of glycosuria to increase along with increasing rates of administration of glucose but as indicated in the figure the variations were too wide to draw any conclusions. The amounts of glucose excreted ranged from 0.5 gram up to 12 to 19 grams in a few instances. In general the losses were quite small ranging from 2 to 6 grams (4 to 12 per cent of the glucose administered), yet they were consistently present and were associated with significant degrees of diuresis.

Total urinary output was measured during the 4 hour period of observation and is shown in Figure 2. The greatest output of urine followed the injection of 5 and 10 per cent glucose in water. The degree of diuresis tended to increase with the amount of glycosuria produced and with the rate of administration but seemed to hold a closer relationship to the type of solution injected. For example the presence of isotonic saline with 5 and 10 per cent glucose decreased greatly the urinary output.

TABLE II—EFFECTS OF INTRAVENOUS SOLUTIONS IN A SINGLE PATIENT

Date 1947	Intravenous solution (cc)	Ra of glucose excretion, gms. /100 cc. /hr.	Amount of urine (cc) in 4 hours	Amount of glucose excreted
8-9	5% glucose in salt	6	1000	
8-10	5% glucose in 5% amino acids	6	70	
8-11	5% glucose in 5% amigen	6	8	
8-12	5% glucose in 5% amino acids	6	730	trace
8-13	5% glucose in 5% amigen	6	900	trace
8-14	5% glucose in saline	6	130	
8-15	5% glucose in water		1000	30.6
8-16	5% glucose in 5% amino acids		1000	8
8-17	5% glucose in 5% amigen		70	30
8-20	Isotonic saline		30	—
8-21	Isotonic saline		250	—

When isotonic saline alone was given an actual hydrating effect was noted, some patients passing as little as 250 cubic centimeters of urine in 4 hours as compared to the usual 600 to 800 cubic centimeters excreted when glucose alone or with saline was administered. The low output of urine with saline is also shown in Table II. 3 injections containing saline produced an output of 280, 240 and 280 cubic centimeters whereas the glucose injections produced an output of 720 cubic centimeters or more. A mild diuretic effect was noted with solutions containing both amino acids and glucose.

The influence of amino acids on glycosuria was studied in 30 injections in which glucose with hydrolyzed protein (amigen) or pure amino acids were given. Six injections were given at rates below 0.5 gram per kilogram per hour and in no case did glycosuria appear (Table II). Twenty four injections were given at rates above .5 gram per kilogram per hour (the rate at which glycosuria consistently appeared when glucose alone was given). In 5 of these 24, no glycosuria appeared and the remaining 19 excreted glucose in comparatively small amounts, ranging from traces to a maximum of 3.8 grams. The presence of amino acids either as such or as hydrolyzed protein (amigen) in some manner effectively reduced the degree of glycosuria as compared with glucose alone given at the same rates. The effect is clearly shown in an experiment car-

ried out in a single patient who was first given concentrated glucose solutions (15 per cent) alone and subsequently in combination with amigen and with pure amino acids administered at the same rates, far above the "threshold" level for glycosuria. A striking reduction in degree of glycosuria was noted when either amino acids or amigen was in the solution (Table II).

With the idea of determining more specifically the nature of the influence of amino acids experiments were carried out in several subjects in which the blood glucose levels were measured at half hour intervals during and following the infusion. Higher blood glucose levels were reached when glucose was given alone than when in combination with amino acids. The hyperglycemia paralleled the degree of glycosuria. This fact tends to indicate that the amino acids act by increasing glucose utilization in the tissues rather than by lowering the renal threshold for glucose excretion. At least, it is apparent that the amino acids in some way enhance the removal of glucose from the circulating blood stream. It was also noted that the effect of pure amino acids in producing a lower curve was more pronounced than that of amigen (hydrolyzed protein) which contains polypeptides as well as amino acids (Table II).

DISCUSSION

From this study it is apparent that glucose given to normal humans in a single controlled intravenous injection is utilized at a rate considerably less than that which Woodyatt and his associates concluded to be normal 32 years ago. This variation may possibly be explained by noting a difference in the method of administration employed. In the present experiments a single liter of glucose solution was given at a steady unchanging rate from the beginning of the injection to its completion. No unnoticed variation in rate could occur for the infusion was under constant bedside observation during the entire period of administration to prevent any changes which might result from shifting of the needle, moving of the subject's arm, or other mechanical factors. Woodyatt and associates on the other hand began each injection at a rate con-

Fig. 2 Urinary output during the intravenous injection of glucose. Each point represents 1 experiment. The effect of saline in reducing urinary output is clearly shown. Note that more than 800 cubic centimeters of urine were excreted only when glucose and water were injected by contrast less than 400 cubic centimeters were excreted in only 3 cases by glucose and water as compared with 9 cases by glucose and saline. See also Table II in which a similar difference was observed.

sidered to be well below that which would produce glycosuria this rate was then increased every half hour until glycosuria appeared. Prolonged continuous injections at constant rates followed this initial stepping up period of administration. It is likely that a lower rate of assimilation would have been observed if Woodyatt had established and maintained a constant lower rate of injection from the beginning especially since our study revealed that glycosuria often did not appear until the second half hour. It is quite conceivable then that Woodyatt and his coworkers might have exceeded the actual rate of utilization and not detected it because of the frequent latency in the appearance of glycosuria.

It is generally believed also that the utilization mechanism is not a static manifestation and that a warming up period is required in order for it to reach its maximum degree of efficiency. Lusk presented the concept that the metabolism of glucose by the tissues tends to increase in the presence of an increased concentration of glucose in the blood stream.

Correspondingly introduction of additional glucose into the blood stream tends to provoke an overproduction of insulin, which then increases the utilization of the subsequent glucose injected. Thus one may bring about a higher rate of utilization by starting infusions at very slow rates and gradually increasing the speed. However the application of such a concept to the clinical usage of intravenous glucose presents certain practical difficulties since fluids ordinarily are given at a more or less constant speed throughout the infusion. The similarity of methods used in this experiment to those in ordinary clinical practice serve to make the findings in this study of practical value.

The hydrating effects of saline in contrast to the diuretic effects of glucose have been observed by Baxter and by Stewart and Rourke who administered massive volumes of intravenous solutions over relatively short periods of time (as much as 5 liters in 4 hours). It is interesting to note that similar effects are evident even in single 1 liter injections.

TABLE II.—EFFECTS OF INTRAVENOUS SOLUTIONS IN A SINGLE PATIENT

Date 1947	Intravenous solution (Lose)	Rate of injection (cc. /kgm. /hr)	Amount of urine (cc.) (4 hours)	Amount of glucose (gram) excreted
1-9	5% glucose in water	6	1080	
1-10	5% glucose in 5% amino acids	6	170	
1-11	5% glucose in 5% amigen	6	8	
1-12	5% glucose in 5% amino acids	6	730	trace
1-13	5% glucose in 5% amigen	6	900	trace
1-14	5% glucose in saline	6	280	
1-15	5% glucose in water		1020	30.6
1-16	5% glucose in 5% amino acids		1020	8
1-17	5% glucose in 5% amigen		1270	20
1-20	Isotonic saline		30	—
1-21	Isotonic saline		280	—

When isotonic saline alone was given an actual hydrating effect was noted some patients passing as little as 250 cubic centimeters of urine in 4 hours as compared to the usual 600 to 800 cubic centimeters excreted when glucose alone or with saline was administered. The low output of urine with saline is also shown in Table II. 3 injections containing saline produced an output of 280, 240 and 280 cubic centimeters whereas the glucose injections produced an output of 720 cubic centimeters or more. A mild diuretic effect was noted with solutions containing both amino acids and glucose.

The influence of amino acids on glycosuria was studied in 30 injections in which glucose with hydrolyzed protein (amigen) or pure amino acids were given. Six injections were given at rates below 0.5 gram per kilogram per hour and in no case did glycosuria appear (Table II). Twenty four injections were given at rates above .5 gram per kilogram per hour (the rate at which glycosuria consistently appeared when glucose alone was given). In 5 of these 24 no glycosuria appeared and the remaining 19 excreted glucose in comparatively small amounts ranging from traces to a maximum of 3.8 grams. The presence of amino acids either as such or as hydrolyzed protein (amigen) in some manner effectively reduced the degree of glycosuria as compared with glucose alone given at the same rates. The effect is clearly shown in an experiment car-

ried out in a single patient who was first given concentrated glucose solutions (15 per cent) alone and subsequently in combination with amigen and with pure amino acids administered at the same rates far above the "threshold" level for glycosuria. A striking reduction in degree of glycosuria was noted when either amino acids or amigen was in the solution (Table II).

With the idea of determining more specifically the nature of the influence of amino acids experiments were carried out in several subjects in which the blood glucose levels were measured at half hour intervals during and following the infusion. Higher blood glucose levels were reached when glucose was given alone than when in combination with amino acids. The hyperglycemia paralleled the degree of glycosuria. This fact tends to indicate that the amino acids act by increasing glucose utilization in the tissues rather than by lowering the renal threshold for glucose excretion. At least, it is apparent that the amino acids in some way enhance the removal of glucose from the circulating blood stream. It was also noted that the effect of pure amino acids in producing a lower curve was more pronounced than that of amigen (hydrolyzed protein) which contains polypeptides as well as amino acids (Table II).

DISCUSSION

From this study it is apparent that glucose given to normal humans in a single controlled intravenous injection is utilized at a rate considerably less than that which Woodyatt and his associates concluded to be normal 32 years ago. This variation may possibly be explained by noting a difference in the method of administration employed. In the present experiments a single liter of glucose solution was given at a steady unchanging rate from the beginning of the injection to its completion. No unnoticed variation in rate could occur for the infusion was under constant bedside observation during the entire period of administration to prevent any changes which might result from shifting of the needle, moving of the subject's arm or other mechanical factors. Woodyatt and associates, on the other hand, began each injection at a rate con-

The data herein presented also indicate that the presence of amino acids accelerates the utilization of glucose by the tissues. The mechanism by which this occurs is not immediately apparent and further study is being carried out in an effort to determine the exact nature of this effect. At present one can only conclude (in view of the associated lowered blood glucose curves) that the change is specifically in the utilization mechanism and not the result of an altered kidney threshold.

SUMMARY

1. With normal adult subjects and commonly employed intravenous glucose solutions given at a uniform rate the maximum speed of injection of glucose without production of glycosuria was found to approximate 0.5 gram per kilogram per hour. This is much lower than the rate of 0.85 gram per kilogram per hour found in normal humans, dogs and rabbits by Woodyatt and his coworkers. In clinical usage this slower rate of injection should be used when intravenous glucose is administered even to patients in a good state of health in order to avoid glycosuria and associated diuresis.

2. Urinary output was considerably reduced when isotonic saline was present in the intravenous solution. Higher concentrations of glucose tended to produce more diuresis than lower concentrations and the amount of diuresis tended to increase with the increased rates of administration.

3. Evidence was obtained that the addition of hydrolyzed protein (amigen) or pure amino acids to the glucose solutions increased the rate of utilization of glucose by the tissues. This was shown by a lower blood sugar level and less glycosuria when amino acids were present than when solutions of glucose alone were given at the same rate.

FETAL MORTALITY AND MORBIDITY IN CESAREAN SECTION

S PEDVIS M.D., J. K. L. IRWIN M.D. and N. W. PHILPOTT M.D., F.A.C.S.
Montreal Quebec

DURING the past decade there has been a changing trend in the type of anesthetic agent used for cesarean section at the Royal Victoria Hospital Maternity Division. The following critical survey of fetal mortality and morbidity has been undertaken to compare the results obtained and to study the underlying factors. Cesarean section was performed in 353 cases during the three periods from July 1, 1940 to December 31, 1941, and from July 1, 1944 to July 1, 1945 and from January 1, 1946 to December 31, 1946. These periods were chosen in order to obtain a sufficiently large group of cases of cesarean section carried out under each of the various anesthetic agents. However the number of sections under general anesthesia is still small because those before 1940 were not included. Previous to this time the present facilities for blood transfusion and the newer chemotherapeutic and antibiotic agents were not available. For the purpose of this discussion the infants have been classified as follows: (1) normal, those perfectly well at birth who remained so until discharge from hospital; (2) morbid, those who required prolonged resuscitation or had respiratory difficulties as shown by cyanosis and labored respirations during the first 24 to 48 hours but who were apparently perfectly well thereafter; (3) dead, nonviable infants still born or those who died shortly after birth.

The data which lend themselves to statistical analysis are presented in the form of contingency tables and have been tested for independence by calculating χ^2 (3). At the foot of each of these tables is the χ^2 value, the number of degrees of freedom (n), the probability (1) from Fisher's Table III of χ^2 and the odds that the observed differences could arise due to chance alone.

In Table I the figures for fetal mortality and morbidity in this series are presented. The term fetal mortality as pointed out by Irving has been used to mean gross fetal mortality which consists of (a) nonviable infants still births and neonatal deaths or (b) just still births or (c) stillbirths and neonatal deaths. In the reports from several large American centers summarized by Irving the fetal mortality using the latter definition ranged from 5.2 to 10.8 per cent. In another group reviewed by Acken the rate ranged from 4.4 to 16.14 per cent, however he did not define his use of the term fetal mortality. The value of 7.3 per cent for gross fetal mortality or 5.3 per cent for stillbirths and neonatal deaths in this compilation compared favorably.

The causes of fetal mortality are enumerated in Table II. It is apparent that prematurity¹ and atelectasis play a major role in causing fetal death. This is in accord with Kohn's series. The large number of premature births in this group can be partially explained by the fact that the indication for cesarean section has made it necessary for the operation to be performed at varying periods before term.

Table III shows the kind of anesthesia that was used in these cases. Since prematurity in itself is such an important factor in fetal mortality the results have also been computed omitting all premature births. The term general anesthesia refers to the employment of (a) cyclopropane or (b) nitrous oxide and ether. In all of these some premedication was given 1 to 2 hours before operation and consisted of one or a combination of the following: atropine, scopolamine, heroin, morphine, barbiturates. Spinal anesthesia refers to a single injection of 1 per cent pontocaine in conjunction with ephedrine hydrochloride 34 grain.

¹ Prematurity in this series is defined as a fetus born at birth with a small number of weeks (or months) of gestation. It is not defined before 10 months of gestation. In this series, these were all included as premature births.

TABLE I.—FETAL MORBIDITY AND MORTALITY FOLLOWING CESAREAN SECTION

No cases		Normal		Morbidity		Total dead		Stillbirths and neonatal deaths	
No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent
11	3.7	249	80	4	1.3	25	7.2	20	5

subcutaneously 15 minutes before and $\frac{3}{4}$ grain repeated immediately before the spinal injection. Local anesthesia refers to the use of 1 per cent novocain. From these figures it appears that general anesthesia gives a slightly higher fetal morbidity and local anesthesia a lowered fetal morbidity but a higher mortality. However the differences are not regarded as significant. The anesthetic agent of choice must not only be most favorable to the fetus but also to the mother. In this series there was only 1 maternal death. The patient had a local anesthetic and death was attributed to uterine hemorrhage. It is of interest that in the last 500 patients who had a spinal anesthetic for cesarean section at the Royal Victoria Maternity Hospital there was only 1 maternal death (6).

The results for full term stillbirths and neonatal deaths are similar to those of Irving. Our results are listed in parentheses after his for the following types of anesthesia: general 4.4 per cent (1.9 per cent) spinal, 4 per cent (2.2 per cent) local 9.7 per cent (4.1 per cent). Allen and Slocum using cyclopropane in 120 cases reported a fetal mortality of 2.5

per cent and a morbidity of 16.7 per cent. Torrie reviewed 120 sections done under spinal anesthesia with 1 per cent pontocaine and obtained a fetal mortality of 5.8 per cent.

Table IV records the type of anesthesia in relation to the various indications for cesarean section. It is obvious that the higher number of toxemias and medical indications for section in the local group could account for part of the increased fetal mortality. However there is a higher number of cases with placenta previa in the general group and of Rh incompatibility and elderly primipara in the spinal group to

TABLE IV.—TYPE OF ANESTHESIA IN RELATION TO INDICATION FOR CESAREAN SECTION

Indications for cesarean section	Type of Anesthesia

account for part of their increases. Therefore in an attempt to find a group that would be more strictly comparable the type of anesthesia in relation to the fetal condition has been analyzed in the cases in which disproportion was the only indication for section (Table V). Although fewer cases are considered than in Table III the same general conclusions appear to hold.

In Table VI an attempt is made to evaluate the effect on the fetus of the type of premedication used for the mother. The cases of spinal, general, and local anesthesia in which the fetus did not have the special management described in the following have been included in this study. It would appear that the opiates given to the mother increase fetal mortality; this is probably due to the narcotic effect on the fetus.

TABLE VI — TYPE OF PREMEDICATION USED FOR THE MOTHER IN RELATION TO THE FETAL CONDITION

and the consequent depression of the respiratory mechanisms. However there is no significant difference between the treatments particularly in view of the fact that a certain bias exists in the indication for the type of premedication.

The high fetal mortality and morbidity rates particularly due to atelectasis in cases of cesarean section prompted the members of the pediatric service in January 1946 to suggest that all these infants be postured with head down perpendicularly for $\frac{1}{2}$ hour after birth and that at the same time the excess mucus be

aspirated from the mouth and pharynx. The latter permits drainage of amniotic fluid and mucus from the respiratory tract and so tends to prevent obstruction by these materials. It was also suggested that oxygen be administered intermittently by mask under positive pressure in an attempt to aid expansion of the fetal lung tissue and to improve oxygenation of the blood. In Table VII two groups similar in all respects except for this special management of the infants are compared. The trend in the data is in favor of this special management but the difference is not significant.

The fetal deaths have been analyzed in relation to the indications for section in the mother and are shown in Table VIII. Fifty per cent occurred in instances in which placenta previa was the reason for section. This emphasizes the importance of hypoxia as a result of maternal blood loss in fetal mortality. The significance of preventing a sudden drop in blood pressure under spinal anesthesia which may impose the deleterious effects of hypoxia in both mother and fetus and the administration of ephedrine to ameliorate this condition is emphasized in Torrie's article.

Fig. 3. Baby being resuscitated on the tilt table. The baby is placed on the heated cot. Note the legs fastened by means of cotton bandage. The hand suction is also being used to clear the air passages.

While these data have not shown a significant difference between treatments, the consistency of the direction of the trend has prompted us to continue this study and to suggest that in order to reduce fetal mortality and morbidity in cesarean sections general or spinal anesthesia without premedication but with the special management of the infants be utilized. With a general anesthetic when the uterus is opened the maternal respiratory system should be cleared of all anesthetic gases and 100 per cent oxygen be given to prevent hypoxia in the fetus. When spinal is used particular care should be taken to prevent fluctuation of fetal blood pressure. In cases in which placenta previa is on for section, transfusions are given to the mother to prevent the oxygenation of the fetus. The oxygenation of the fetus is caused by the oxygenated blood.

TABLE VIII — FETAL DEATHS IN RELATION TO INDICATION FOR CESAREAN SECTION

Cervical cardiac	1	10
Disproportion	1	10

sistent with the particular indication for cesarean section

The following routine is recommended in handling infants delivered by cesarean section

1 Have a pediatrician present to receive the infant from the obstetrician

2 Place the infant in a heated crib and cover with a previously warmed blanket

3 Hold the infant perpendicularly with the head down for 20 to 30 minutes or tie the infant to a tilt table as designed by one of the authors (Fig. 1). This is particularly useful when the infant needs resuscitation since the rocker method may be employed by tilting the table up and down. Oxygen can be given by mask at the same time

4 Aspirate the mucus and amniotic fluid from the nose, mouth and pharynx. One may use a rubber catheter with a glass trap. However, this has the disadvantage that occasionally bacteria from the doctor's upper respiratory passages may reach the infant and vice versa. One of the authors has designed a hand suction apparatus (Fig. 2) which prevents this difficulty. These are used in preference to the various mechanical suction types of apparatus which are connected to the resuscitation machines because we have found the strong suction in the latter can injure the oral and pharyngeal mucous membrane of the infant. The frequent application of the catheter to the posterior pharynx may also initiate vomiting. If this occurs when the doctor is present he can remove the fluid, whereas if it should occur when the infant is alone in its crib some of the vomitus may be aspirated into the lower respiratory tract

5 Administer oxygen intermittently by mask.

6 Perform routine care such as the administration of vitamin K intramuscularly and the instillation of silver nitrate solution to the eyes

7 Return all infants to the premature ward for careful observation and tilt the crib to an angle of 45 degrees and place the infant in crib so that the head is at the lower end for a period of 12 hours

SUMMARY

1 In 357 infants delivered by cesarean section the gross mortality was 7.3 per cent and the morbidity 11.2 per cent

2 Of the fetal deaths prematurity and atelectasis accounted for 36.6 and 29.3 per cent respectively

3 Fetal mortality in cesarean section was high due to the maternal complications which necessitated the operation. Spinal anesthesia has not appreciably affected the fetal mortality but it has definitely lowered maternal morbidity and mortality

4 Disproportion was the principal indication for section

5 Premedication in the form of morphine, heroin or ephedrine appeared to have an adverse effect on the fetus but the difference was only slight.

6 Special management of the infant at birth tended to reduce the fetal mortality and morbidity

7 Of the fetal deaths, 50 per cent occurred in those cases in which placenta previa was the indication for section.

8 A method for handling infants born after cesarean section is described

PROLAPSE OF REDUNDANT GASTRIC MUCOSA

ARTHUR M. COVE, M.D. I. WILFRED C. CURRIE, M.D., M.S., F.A.C.S.
Stockton, California

In the past the presence of hypermobile redundant gastric mucosa has been such a common and incidental finding by surgeons and roentgenologists that little significance was placed upon it as an etiological factor. Consequently no attempt was made to correct the condition. Since Scott in a recent article gave impetus to the study of this problem more and more writers are beginning to recognize its significance as a clinical entity and as the cause of many otherwise unexplained gastrointestinal complaints. It is difficult to understand why this condition should have been so universally overlooked in the past in patients with gastrointestinal disease.

Bockus still believes that only severe prolapse associated with gastritis can cause symptoms and then only after producing partial pyloric obstruction. He also feels that gastric symptoms from this source are so rare that they have no practical significance. Others also believe that this lesion is of no particular significance and some roentgenologists do not report this abnormality. On the other hand Melamed (4) has collected 25 cases of prolapse with symptoms all relieved either by medicine or surgery.

During the past year we have observed no less than 22 such patients with symptoms which were otherwise unexplained, 5 of whom came to surgery. All 5 patients operated upon have experienced relief from symptoms and a more detailed analysis will be given later. In 1926 Ellason, Pendergrass and Wright first described the roentgen signs produced by prolapse of gastric mucosa. In Melamed's (7) original article in 1943 he was able to find only 19 proved cases in the literature and published a report of 1 case of his own, a total of 20 cases. On the other hand Archer states that prolapsing gastric mucosa is not rare but he gives

no figures. Feldman indicates that redundant gastric mucosa occurs in approximately 1 per cent of all patients with gastrointestinal tract disease and points out that the condition is not recognized until mucosa prolapses into the pyloric canal or into the duodenal cap. In Scott's survey of this problem 19,228 hospital admissions were analyzed. Roentgenological examinations of the upper gastrointestinal tract were made in 1,346 of these patients which revealed the presence of gastric ulcer in 13 or 0.96 per cent, duodenal ulcer in 325 or 24.1 per cent, duodenitis in 17 or 1.3 per cent, prolapse of redundant gastric mucosa in 14 or an incidence of 1.04 per cent, gastric tumors in none. In our series of patients upon whom an upper gastrointestinal tract examination was made the incidence of prolapse of gastric mucosa was even greater. A review of 650 consecutive examinations revealed that prolapse had occurred in 22 cases, a percentage of 3.38. This corroborated our original impression that the incidence is greater than usually suspected.

In the past prior to the development of our interest in the presence of this lesion this diagnosis was overlooked in many cases because first, the examiner was unaware of the significance of the finding, second filling defects produced by prolapse were confused with those due to other conditions, and third when recognized the condition was believed to be of no clinical importance and an attempt was made to explain the clinical symptoms on some other basis.

SYMPTOMATOLOGY AND PHYSICAL FINDINGS

Patients with prolapse of redundant gastric mucosa complain of a variety of symptoms which usually are influenced by the extent and the condition of the prolapsed mucosa. These symptoms are never characteristic and do not permit a clinical diagnosis of the disorder. As a general rule the diagnosis must be made on

From C. Corbrey Clinic, Stockton, California, and San Joaquin General Hospital, L. French Clinic, C. Corbrey, California.

the basis of roentgenologic findings after elimination of the presence of all other gastrointestinal lesions. Likewise the objective physical findings are indecisive with the exception of a palpable tumor mass in the epigastrium in the region of the pylorus. Such a mass is characterized by its soft doughy consistency associated with free mobility and with a very characteristic sensation to the examining fingers when the prolapse is reduced. This palpable quality can be likened only to that of a hernia during the process of reduction under the palpating fingers. This sensation no doubt is caused by the sliding of the prolapsed gastric mucosa back through the pyloric ring and its finding on physical examination is pathognomonic of the lesion just as the similar findings of a soft tumor mass in the groin which can be reduced back into the abdominal cavity through a small defect in the abdominal wall with a mucous gurgling sensation is pathognomonic of hernia. In 2 of our patients reported in this series this finding was present on numerous occasions. And in each case immediately after the reduction of the prolapsing mucosa through the pyloric ring by the examining fingers the palpable tumor could no longer be demonstrated.

The only other physical finding of any consequence is the occasional presence of mild tenderness in the region of the pylorus which of course is an incidental finding and may be associated with numerous lesions in this region.

The major symptoms therefore of which these patients complain are intermittent epigastric distress with cramping pains no doubt based on partial pyloric obstruction varying relationship to food sense of fullness bloating and heart burn nausea and vomiting gastrointestinal hemorrhages. The disorder should be suspected in any patient with an atypical ulcer history in whom there is not a satisfactory response to ulcer regimen and in those with repeated recurrences when placed on solid foods as well as in those with recurrent functional complaints and with recurrent small or large gastrointestinal bleeding which cannot be explained on any other basis.

As a general rule the routine laboratory examination of the blood and urine reveals no abnormality. Secondary anemias due to pro-

longed intermittent bleeding may be found in some patients. Scott reports that in over two-thirds of the patients gastric analyses show results within normal limits in one-third hyperchlorhydria is revealed. Persistent occult blood in the stools may be found in many of these patients.

Gastroscopic examination was done on one of our patients and no abnormality discovered. Similarly those who report the findings on gastroscopy do not indicate that any significant evidence may be obtained by this method. However the principal value of gastroscopy in these cases lies in the ruling out of other gastric lesions which may be missed by roentgen examination.

DIAGNOSIS BASED ON ROENTGENOGRAPHIC FINDING

The diagnosis of prolapse of the gastric mucosa into the duodenum should be suspected from the clinical history and on occasion from the physical findings. However the appearance at fluoroscopy and on examination of the roentgen films is quite characteristic and the condition is easily recognized by the roentgenologist if the pathology of the disorder and the following features are kept in mind.

Characteristically prolapse of redundant gastric mucosa into the duodenal bulb is represented by a central filling defect near the base of the bulb most often lobulated. This gives a mushroom or cauliflower like appearance which may vary somewhat in extent and configuration on the same and different examinations. In our experience the defect has been more readily demonstrated in the horizontal than the erect position. In most instances the defect is traversed by lines of increased density which can be followed into the stomach and are continuous with the gastric rugae. In uncomplicated cases the outline of the bulb is smooth and fluoroscopically no irritability or spasm is noted. Point tenderness has not been a frequent finding. In several of the cases some narrowing of the pylorus has been noted suggesting hypertrophy. Although seen in a number of the cases hyperperistalsis has not been constantly associated. There were no craters seen, and no patients had gastric

lesion, many factors have been suggested which may contribute to its occurrence. An enumeration of these factors may be set down as follows: first the presence of a small unrecognized mucosal ulcer which results in the hyperplasia of the gastric mucosa (Bralow and Melamed 4); second the presence of hypertrophic gastritis (Bockus); third persistent hypermotility of the stomach; and fourth congenital variation in the anatomy of the stomach structure consisting of a gastric mucosa which is abnormally hypermobile on the surface of the gastric muscularis.

All of these factors seem to be adequately summarized by Scott who points out that the one common denominator in the theories regarding the etiology of prolapse is an abnormal disturbance of gastric peristalsis and function. The most common continuous and effective means of altering gastric functions springs from the effects of emotions and the nervous system on gastric motility. Consequently in view of the construction of the stomach walls which normally permit some degree of mobility between them, it seems possible that certain neurogenic factors are the inciting cause of a disturbed gastric function that ultimately brings about a mucosal prolapse. This fact becomes more possible when one bears in mind that secretory as well as motor activities of the stomach are definitely correlated through Meissner's plexus located in the submucosal coat of the stomach. The pre-existing disease process of the gastric mucosa is not necessary for the production of a prolapse. Melamed is inclined to support this theory and indicates that since the muscularis mucosa is known to have muscular activity independent of that of the main musculature of the stomach, it is entirely possible that neurogenic factors are the inciting cause of a disturbed gastric function that ultimately brings about a prolapse. He further points out that it has been repeatedly shown that emotion such as worry, fear, excitement, and anger alter not only gastric chemistry but also peristalsis.

In considering the fourth and most important factor in the etiology of the lesion, namely the abnormal hypermobility of the gastric mucosa on its muscularis which may

Fig. 2. Case 2. Large lobulated defect in the bulb, but the contour of the bulb is maintained. Appearance is similar to that of polypoid growth.

be either a congenital characteristic or an acquired lesion. Melamed points out the following facts. In the first place, in the normal gastric antrum, the mucosa and muscularis are connected by soft yielding submucosa composed of loose areolar tissue containing blood vessels, lymphatics, and nerves. This explains a certain amount of limited mobility of the mucosa on the muscularis as is found in all normal stomachs and may be easily demonstrated at autopsy. Scott points out that in his study of over 100 fresh stomachs, normally the extent of this movement was not sufficient to permit a prolapse, and that in those few cases in which a prolapse could be produced, the previous history of the patients indicated that they actually had had gastric symptoms. Melamed was not able to confirm this observation since in several cases which he witnessed, the gastric mucosa could be pulled

Fig. 1. Case 1. Large central defect at the base of the bulb (arrow) demonstrating the gastric mucosa faced to the defect.

resulted at 6 hours. It is well to attempt to classify the degree of prolapse (mild, moderate and marked) as this may be of some clinical value.

Differential diagnoses. (1) Prolapsing polypoid tumor of the pyloric end of the stomach. It is possible that at times a definite differentiation cannot be made. The tracing of the rugal fold into the defect, however, should aid considerably in establishing the diagnosis. Also in prolapse there will be no defect seen at any time on the gastric side of the pylorus. (2) Hypertrophy of the pyloric sphincter. In this condition there is a curved pressure defect on the base of the duodenal bulb but no area of radiolucency is seen. The umbrella appearance which has been described in this lesion has been found to be present in prolapse more frequently than one would expect normally. This is probably due to the fact that in prolapse hypertrophy of the pylorus takes place

(3) Duodenitis. As has been mentioned before the lack of spasm and irritability of the bulb should establish the differentiation. Likewise instead of the rugal pattern being enlarged and irregular it is more apt to be compressed. (4) Duodenal ulcer. In prolapse the margins of the bulb are smooth even in cases of marked degree. In our present series there have been 2 cases of a associated duodenal ulcer and prolapse of gastric mucosa. In 1 of these a gastric enterostomy was performed 20 years previously for the ulcer. When these two conditions coexist in addition to the central defect one notes a deformity of the contour of the bulb or a crater. (5) Hypertrophic gastritis. In this condition the enlarged gastric rugae may enter the bulb but in addition to evidence of disease in other portions of the stomach gastroscopy should readily reveal the true nature of the condition. (6) Polyps of the duodenum. These are infrequently found. When present they may be in other places than at the base of the bulb. The gastric rugae will not be traced into the defect.

In the past it is probable that prolapse has masqueraded as one of the above conditions mainly because we have not been alert and aware of this entity. The roentgenologic appearance however is sufficiently characteristic to establish the diagnosis.

TREATMENT AND RESULTS

Treatment of the vast majority of these patients may satisfactorily be confined to medical measures and in slight and moderate prolapses frequent small feedings of a bland diet usually afford relief. In some hospitalization, rest in bed and freedom from tension associated with the elimination of all condiments as well as tobacco, alcohol and caffeine will effect some degree of relief from distress. On the other hand there is little reason for one to assume that such relief will be permanent. Although the etiology of this lesion is not clear the pathology is definite enough for one to conclude that the lesion rests purely on a mechanical basis and once established will in all probability receive no permanent relief short of mechanical correction. Regarding the etiology and pathology of the

lesion many factors have been suggested which may contribute to its occurrence. An enumeration of these factors may be set down as follows: first the presence of a small unrecognized mucosal ulcer which results in the hyperplasia of the gastric mucosa (Bralow and Melamed 4); second the presence of hypertrophic gastritis (Bockus); third persistent hypermotility of the stomach; and fourth congenital variation in the anatomy of the stomach structure consisting of a gastric mucosa which is abnormally hypermobile on the surface of the gastric muscularis.

All of these factors seem to be adequately summarized by Scott who points out that the one common denominator in the theories regarding the etiology of prolapse is an abnormal disturbance of gastric peristalsis and function. The most common continuous and effective means of altering gastric functions springs from the effects of emotions and the nervous system on gastric motility. Consequently in view of the construction of the stomach walls which normally permit some degree of mobility between them it seems possible that certain neurogenic factors are the inciting cause of a disturbed gastric function that ultimately brings about a mucosal prolapse. This fact becomes more possible when one bears in mind that secretory as well as motor activities of the stomach are definitely correlated through Meissner's plexus located in the submucosal coat of the stomach. The pre-existing disease process of the gastric mucosa is not necessary for the production of a prolapse. Melamed is inclined to support this theory and indicates that since the muscularis mucosa is known to have muscular activity independent of that of the main musculature of the stomach it is entirely possible that neurogenic factors are the inciting cause of a disturbed gastric function that ultimately brings about a prolapse. He further points out that it has been repeatedly shown that emotion such as worry, fear, excitement and anger alter not only gastric chemistry but also peristalsis.

In considering the fourth and most important factor in the etiology of the lesion namely the abnormal hypermobility of the gastric mucosa on its muscularis which may

Fig. 2. Case 2. Large lobulated defect in the bulb but the contour of the bulb is maintained. Appearance is similar to that of polypoid growth.

be either a congenital characteristic or an acquired lesion. Melamed points out the following facts. In the first place in the normal gastric antrum the mucosa and muscularis are connected by soft yielding submucosa composed of loose areolar tissue containing blood vessels, lymphatics and nerves. This explains a certain amount of limited mobility of the mucosa on the muscularis as is found in all normal stomachs and may be easily demonstrated at autopsy. Scott points out that in his study of over 100 fresh stomachs normally the extent of this movement was not sufficient to permit a prolapse and that in those few cases in which a prolapse could be produced the previous history of the patients indicated that they actually had had gastric symptoms. Melamed was not able to confirm this observation since in several cases which he witnessed the gastric mucosa could be pulled

Fig. 3. Case 3. Large ventral defect in the duodenal bulb. The gastric rugae readily demonstrated passing through the defect.

through the pylorus with a forceps and he intimated that a gastric mucosa could be pulled through to correspond with Scott's description of a small prolapse.

Obviously the lesion then is a mechanical one based on a hypermobility of the gastric mucosa which may be congenital in nature or may have been produced by abnormal gastric motility which over a period of time loosens the attachment of the mucosa to the muscularis to such an extent that a prolapse can occur. In all probability such a lesion cannot correct itself but must be corrected by mechanical means such as removal of the redundant mucosa or adequate anchorage of the mucosa to the muscularis.

This does not preclude that all such patients must be treated surgically since a vast majority of them can live comfortably and without symptoms by simple medical management as previously pointed out. We must therefore consider the logical indications which justify surgical treatment. The essential factors which influence a decision with respect to the advisability of surgery are first, the persistence, severity and intractability of symptoms. In other words, if the symptoms

Fig. 4. Case 4. Irregular duodenal defect at the base of the bulb. The finger passes through the defect and the duodenal lumen is demonstrated.

are persistent and intractable to medical management the patient as well as the surgeon will in all probability be inclined to seek more drastic means of relief. The second essential factor is that of pyloric obstruction to the extent that recurrent persistent vomiting may occur which is associated with the failure of the patient to maintain his normal weight. Obviously such a lesion is disabling and interferes with the body physiology to the extent that partial starvation is present. It therefore warrants the risk of surgical intervention for its correction. The third essential factor one we believe important is repeated gross gastrointestinal hemorrhages experienced by an occasional patient or a secondary anemia resulting from repeated small bleeding. Such patients obviously require surgical correction of the lesion since hemorrhage can occur to such a great extent as to endanger life. In 2 of our patients such a problem was present.

SURGICAL ASPECTS

a Surgical correction of these lesions is usually accomplished by resecting a generous portion of the redundant gastric mucosa following which some type of an adequate pyloroplasty is done. Such a procedure is recommended by Bohrer and Copleman. Rees recommends not only antral gastrotomy with excision of the redundant mucosa and pyloroplasty but also anchorage of the mucosa to the muscularis and section of the pyloric muscle. A similar type of procedure is suggested by Archer and Cooper. Scott and Bralow and Melamed. Recently more radical procedures have been suggested. Norgore, Martin and Schuler reported 2 instances in which they did a Finsterer type of retrocolic enterogastric anastomosis following a partial resection of the stomach. In our patients who came to surgery the procedure has been one of antrotyomy with division of the pyloric muscle resection of an abundant portion of the prolapsing gastric mucosa followed by a Horsley pyloroplasty or Finney pyloroplasty. We have not felt justified in doing the more radical procedure of partial gastric resection.

b *Findings at operation.* Upon celiotomy in a case of suspected prolapse of the redundant gastric mucosa it is essential that certain findings be present before one is justified in carrying out an extensive surgical procedure. The following exploratory maneuvers are done before a final decision is arrived at. First, the stomach is adequately exposed and the pylorus and duodenal bulb are gently palpated. In most cases if prolapse is present, a soft doughy mass is distinctly palpable in the duodenal bulb. By gentle taxis this mass is reduced through the pylorus into the stomach and can be reproduced by a gentle milking action on the pyloric end of the stomach. Such a finding is pathognomonic of the lesion. On the other hand if palpation of the stomach reveals a prominent folded gastric mucosa in the pylorus which does not at the time produce an actual prolapsing mass into the duodenal cap, one is justified in doing an antrotyomy. The gastric mucosa is then tested for hypermobility by securing a fold of the mucosa by means of the forceps placed well above the pyloric sphincter. By this means a hyper-

mobile gastric mucosa may be easily pushed through the pyloric sphincter into the duodenal cap and may readily produce a typical prolapse. If this finding is present one is justified in resecting a generous portion of the mucosa which is readily done by raising a large fold of the posterior gastric mucosa between two Allis forceps and applying a clamp at the base of this folded mucosa longitudinal to the axis of the stomach and crossing the pyloric sphincter. The cut edges of the mucosa are then approximated by atraumatic catgut suture which may on occasion include a small portion of the gastric muscularis so that adequate anchorage is effected.

ANALYSIS OF CLINICAL ASPECTS
IN OUR CASES

Analysis of the clinical aspect in 20 cases (2 ulcer patients excluded) revealed. The average age was 49 years the youngest being 26 the oldest 64. Fourteen were males 6 were females. Twelve were obese 5 were slightly overweight. Eighteen were white 2 negro. History of overindulgence of alcohol was present in 5 cases.

The average duration of symptoms was 2 to 3 years. Abdominal pain or discomfort was the most common complaint. This varied considerably both as to type and location. Pain was relieved by food in 4, aggravated in 8 not related in 5 and indefinite in 3. Seven stated that pain was aggravated by fatty foods spices and alcohol. Vomiting was a prominent symptom in 3 cases fairly frequent in 4. There was a history of more than 3 massive bleeding episodes in 2 cases 3 others gave a history of hematemesis or tarry stools.

RELATION OF SYMPTOMS TO DEGREE OF
PROLAPSE

There were 6 cases classified as mild prolapse 7 as moderate and 7 as marked. In the patients whose symptoms were controlled poorly by diet 4 had marked prolapse 2 moderate and 1 mild. As to severity of symptoms in the 6 cases classified as mild prolapse, 5 patients had vague complaints in the 7 cases of moderate prolapse 5 patients had both some symptoms 6 of the 7 patients with severe prolapse had severe symptoms (The remain

ing patients only complaint was repeated gastrointestinal hemorrhages.)

CASE HISTORIES

CASE 1. F. S., 45 year old white male, complained of pain in the upper abdomen of several years duration. The pain consisted of recurring cramps following meals. Other history was essentially negative. Patient did not respond to a medical regimen. He was operated on and a resection of redundant gastric mucosa associated with Finney type of pyloroplasty was performed. Patient has now been free of complaints for 1 year.

CASE 2. C. N., 35 year old female, had repeated attacks of nausea and pain in the upper abdomen of 4 to 5 years duration. In the past few months she had developed nocturnal vomiting. The pain was aggravated by food intake particularly solid foods. There was some weight loss. The patient was operated on a large quantity of redundant gastric mucosa was removed and a Finney type pyloroplasty was performed. Following operation gastric complaints disappeared. The patient has gained weight as a result of her ability to eat any type of food.

CASE 3. W. C., 32 year old negro male had a 4 year history of burning pain in the epigastrium occasionally relieved by food occasionally aggravated by food. Gas and sour stomach were also present. Vomiting occurred at infrequent intervals. There was a history of several episodes of frank hematemesis and tarry stools. In the past he had been told he had a duodenal ulcer and had received some benefit from an ulcer diet. Following operation (resection of redundant gastric mucosa and pyloroplasty) the patient had complete relief from symptoms. (Incidentally, no ulcer was found at operation.) Six months later the patient returned with a history of vague abdominal distress for 2 to 3 days followed by hematemesis and tarry stools. Gastrointestinal series at this time revealed a deformed bulb and pylorus which was considered to be secondary to the pyloroplasty. Hemorrhage may have been due to a shallow ulcer at the suture line. The patient treated conservatively has been symptom free for 3 months.

CASE 4. D. M., 61 year old white male, has been suffering from generalized rheumatoid arthritis for many years. He had a history of massive hematemesis 6 times in the last 5 years. Numerous previous gastrointestinal studies were said to be negative. There were no other gastrointestinal complaints. The patient was operated on and resection of redundant mucosa and Horsley pyloroplasty were performed. It has been only 3 months since operation. The patient states however that he can now recognize that he did have some abdominal distress prior to the operation which is no longer present.

CASE 5. T. H., 54 year old female complained of stomach trouble for the past 4 to 5 years. Pain was

present in the upper abdomen aggravated by food intake. No relief was obtained from diet or other medical measures. The patient was operated on, redundant gastric mucosa existed, and a Hebecker-Mikulicz pyloroplasty was performed. Since the operation the patient has been entirely free of symptoms.

CONCLUSIONS

1. Prolapse of gastric mucosa is more common than generally suspected.
2. The diagnosis can only be established roentgenologically since the clinical picture is extremely variable.
3. Mild degrees of prolapse rarely produce symptoms and probably are only an incidental finding.
4. Moderate or marked degrees of prolapse are often associated with complaints of sufficient severity to cause the patient some degree of disability.
5. The most common complication of prolapse is gastrointestinal hemorrhage.
6. The symptoms of prolapse can be controlled medically in the majority of instances.
7. With symptoms of sufficient degree failure of response to medical treatment is an indication for surgical treatment. Surgery is also indicated in those patients who have had repeated severe gastrointestinal hemorrhage.
8. The surgical procedure of choice is the simplest which will correct the lesion—antrotomy with removal of redundant gastric mucosa combined with some type of pyloroplasty.

INDURATED LEG AND LEG ULCERS

A Clinical Study of Their Etiology and Treatment

HOWARD MAHORNER, M.D., F.A.C.S. New Orleans, Louisiana

THE purpose of this presentation is to record conclusions and opinions on indurated leg and leg ulcer arrived at after a large experience over a period of some 20 years in the management of vascular diseases affecting the lower extremity. Included in this clinical experience are numerous cases of varicose veins, indurated legs, leg ulcers, thromboangitis obliterans and other vascular diseases. After many years of working with these problems one is bound to reach certain crystallized conclusions at times conflicting sharply with views frequently expressed in the literature at other times in perfect agreement with commonly recorded doctrine.

An attempt will be made to present the subject as a composite problem intensely complex and including all the various factors which might influence the lower extremity ultimately to become the seat of some pathologic process which leads to induration and then ulceration. When any individual problem of this sort presents itself the potentialities of its causes and treatment, if viewed broadly and more or less completely will help in its solution. Each individual problem is usually very intricate and does not represent merely one phase with out variations or influencing factors other than those immediately apparent. It is important to think of these problems in a projected fourth dimension not only what the leg looks like objectively now but what it will look like in 15 or 20 years unless certain component causes which have influenced it and which will continue to influence it in the future are changed. When one sees a small leg ulcer particularly on a young individual or a post thrombophlebitic edema 2 months after a deep vein thrombosis has occurred it is helpful to

think of other cases of this type but 15 years farther advanced. Thus the course of the new case of postthrombophlebitic edema may be projected into the future with its complications and end results. With such consideration it is possible to envision various measures and advices which may be given to prevent as far as possible the development of more advanced stages of the same process.

If a doctor is to manage such a problem in an optimum manner, not only must he have knowledge of the various therapeutic measures which may be employed, but he must view even the minor processes such for example as varicose veins with a little scaly dermatitis near the internal malleolus not only as a stationary pathologic condition but as one whose factors will continue to operate chronically over a long period of time. These diseases are all chronic. They may be seen in an early or late phase but almost invariably the tendency for them is to progress and to become more severe. This is a basic truth which when firmly realized must strongly influence the doctor in his instruction to the patient and in his judgment as to the therapy for the condition as it presents itself before him.

By indurated leg is meant any hardness or thickening of the skin and subcutaneous tissue resulting from edema. Positive factors which influence the development of indurated leg and ultimately leg ulcer may be grouped under nine headings in this classification based on etiology: (1) postthrombophlebitic edema (2) varicose veins (3) obesity (4) trauma, (5) infection (pyogenic or fungus), (6) lymphedema (7) immersion leg (8) arteriovenous communications (9) systemic causes.

Usually any indurated leg has at least two and sometimes three or four of these different factors responsible for its development. Frequently trauma is an additional factor in the development of an ulcer on a leg which has

Read at the meeting of the staff of the United States Marine Hospital, Mobile, Alabama, October 24, 1947.
From the Surgical Services of Dr. Howard Mahorner, Baptist Hospital and Touro Infirmary, New Orleans, Louisiana.

long been the seat of postthrombophlebitic edema. Less often three factors such as varicose veins, obesity, trauma, and sometimes a fourth invasion of trichophyton, are found as responsible etiologic causes in the same patient. Perhaps the most interesting of all the problems of leg ulcer and indurated leg are those in which the underlying primary cause is something far removed and of a systemic nature for example cardiac decompensations resulting from goiter may be an incipient factor in the development of the leg condition. Often these patients are not aware that the onset of their leg trouble is so indirect.

In the management of these patients of course it is very important to have a detailed history and very carefully done physical examination and preferably to look at the problem not once but at several different times. Often this will lead to a more accurate conclusion and thus facilitate judgment in the treatment. In selecting different measures for treating an individual case it is well to review again the different factors which are responsible for such changes in the leg. Each and every one of them should be obviated as far as possible. Sometimes an attempt to control a condition of this sort is ineffectual when the treatment is directed against the most obvious factor only and when other causes, less obvious, but nevertheless very potent are left alone.

One ought to be well aware of the many different therapeutic measures which can be used locally systemically and regionally in controlling these lesions. These too may be classified under a number of different headings as follows:

Position—rest

- a. Elevation
- b. Intermittent recumbency—interruption of period of leg dependency
3. Local pressure
 - a. Unna paste boot
 - b. Compression bandages, ace type—sponges
 - c. Elastic stocking
3. Local applications to ulcer

Dyes—(3% aqueous solution gentian violet; scarlet red), zinc oxide; zinc peroxide; bismuth powder; dried red blood cells, tyrosyltyrosine, sulfonamide crystals; sulfathiazole and urea, penicillin, streptomycin and many other medications.
4. Temperature (optimum—neither cold nor heat, room temperature)
5. Chemical or operative interruption of the sympathetic nerve impulses resulting in vasodilatation.

6. Systemic therapy—antithrombotic therapy cardiac therapy other drugs and operations directed to correction of a systemic factor. Systemic vasodilators tetraethylammonium chloride ether alcohol, tocopherol
7. Anticoagulants
 - a. Dicumarol
 - b. Heparin
 - c. Heparin in Piliin menstruum leeches
8. Ligation of veins
9. Grafting of ulcers with or without excision of ulcer bed
- a. Konikoleon or similar operation with or without skin grafts

When a knowledge of the range of effective measures is considered with the factors responsible for the indurated leg the proper outline of the management of the case may become very problematic and interesting, challenging one's information judgment, and technical ability. Certainly the treatment is something more than just dressing a leg ulcer.

TREATMENT

The treatment for indurated leg and leg ulcers can be divided into preventive and active. This involves a very broad scope for in reality prevention of indurated leg means the prevention of anything which might create a persistent or recurrent edema of the leg. Preventive treatment includes the consideration of all approaching factors which ultimately might lead to persistent swelling of the leg including the prevention of excessive obesity postoperative thrombosis, trauma to the leg infection and other such factors. The prevention of the indurated leg necessitates also the consideration of the means of removal of factors which have already been established and which created edema in the leg. It involves the knowledge of the active measures which might be employed at the time of thrombosis of the deep veins of the extremity.

The physician and patient must have the proper regard for danger signs such as edema persisting after injury from even slight trauma. If allowed to recur day after day this may result in a hard area and years later in a spreading induration with eventual ulceration whereas if it is taken care of promptly and properly with adequate rest at the time to permit the tissues to heal, the condition may subside and disappear entirely. It is well to recall that the tissue vitality of the skin varies at different

regions of the body. On the face and neck an incised wound heals very rapidly. The blood supply is good, the vitality of the skin is comparatively high and it is feasible to remove stitches early. On the other hand, on the abdomen the skin heals much less readily and stitches must be left in longer. The vitality of the skin in the region of the ankle is the lowest for any region of the body. Incised wounds heal slowly here, bruises disappear less readily and swelling has the tendency to persist longer. It is natural for a patient to regard a furuncle of the hand and a furuncle in the region of the ankle of similar importance. Such however is not the case. A furuncle in the region of the malleolus particularly in an obese individual may result in a thickened, hard, subcutaneous area with spreading induration. To heal a lesion of the leg requires more time and rest with intermittent recumbency than it does to heal a similar lesion in the region of the wrist. If proper regard is not had for these physiologic facts the patient with edema of the ankle resulting from an infection due to trauma or furunculosis may have this edema persist day after day with attendant induration of the leg in that area.

POSTTHROMBOPHLEBITIC EDEMA AND ULCER

Postthrombophlebitic edema ulcers are among the most common ones seen in private practice. The reason for this becomes apparent after a little study and consideration. Varicose ulcers which are also common usually can be healed by external pressure or by operation to ligate the veins. Compression bandages or elastic stockings are appliances employed successfully by patients with varicose veins and varicose ulcer. Usually the ulcer will respond to such therapy because the compression appliance not only prevents edema by pressure on the ulcer but in addition to that it compresses the varicose veins and prevents the retrograde flow of blood. In other words it improves the circulation. On the other hand ulcer resulting from postthrombophlebitic edema is not as readily improved with external pressure. The edema there is due not to retrograde flow as in varicose veins, but it is back pressure attributable to two

factors obstructed return channels increasing the intercellular pressure and dependency of the part which adds the gravity factor to the already increased intercellular fluid. Postthrombophlebitic ulcers are usually very painful and the patients complain bitterly and suffer from them. They are not well tolerated even by indolent individuals.

The preventive treatment of postthrombophlebitic edema of course is to prevent the thrombosis. One of the most effective advances made in this regard is the employment of 'early ambulation'. Undoubtedly getting patients out of bed early after operation and parturition is a big help in preventing thrombosis in the veins of the lower extremity. Active movement in bed, leg exercises are physical factors which also help to prevent thrombosis. It has long been realized that getting a patient up early after ligation of varicose veins will reduce the incidence of pulmonary embolism. Only more recently has this same trend been widely used for most other surgical operations.

Anticoagulants in the prevention and treatment of thrombosis have their advocates, and justly so. There is ample evidence reported by men who have used these drugs in large numbers of cases to show that the instance of thrombosis and pulmonary embolism is remarkably reduced by their employment (Allen, E. V. Jorpes). These drugs are used more often as a therapeutic than as a preventive measure. Reports of their effectiveness in preventing the propagation of a thrombus and in the prevention of pulmonary embolism compares favorably with the results of surgical measures for this same purpose.

To prevent pulmonary embolism in elderly individuals preliminary deep vein ligation preceding a major operation has been used and advocated by the Massachusetts General Hospital Group (Allen, Arthur). As a method for active treatment of thrombosis of the deep veins of the lower extremity, ligation of the femoral or iliac veins is being enthusiastically employed in some institutions and ignored in others. This measure has not been wholly accepted by the profession but it deserves a proper place. A most important consideration is whether interruption of the deep veins at

the time of thrombosis will lessen the magnitude of postthrombophlebitic edema or increase it. My experience leads me to believe that interruption of a deep vein in the thigh never can be done with absolute impunity. There is always some residual edema from interruption of the femoral vein. This may not be apparent on restricted activity but it becomes apparent on forced activity. If a patient who has had such a ligation had to work a period of 16 or 18 hours a day the edema would most assuredly manifest itself long before the end of the day. In reality the return circulation in an extremity in which the femoral vein has been transected is always less efficient than it is in a normal extremity. But the question as to whether operation increases or diminishes the tendency to edema after thrombosis has occurred has not been definitely determined. It possibly increases it if the thrombus is small and diminishes it if the thrombus is massive provided in each instance the thrombus is removed at the time of ligation. When there is an extensive thrombus involving a long segment of the femoral vein with massive edema of the leg transection of the vein and removal of the thrombus with ligation may permit better development of collateral circulation during convalescence and eventually a more efficient return circulation than if the huge thrombus is left there to organize and obstruct a larger segment of the vein. My own indications for interrupting the femoral vein for thrombosis are two: when any sign of pulmonary embolism has manifested itself ligation is immediately done to prevent a major embolus; second when there is an extensive thrombosis resulting in a massive swelling of the leg the thrombus is removed and the vein is ligated with the intention of diminishing postthrombophlebitic edema.

The active treatment for postthrombophlebitic edema is a question of much debate. It demands a selection from numerous different measures, none of which are entirely specific. The results are not uniform, sometimes surprisingly good but sometimes disheartening. This regards only the well established edema in the chronic stage following thrombosis of the deep veins of the lower ex-

trinity. It is a fact but rarely acknowledged that the return circulation of these extremities can never be expected to assume a perfectly normal capacity. In addition to this the resolution of the process involving as it does the development of collaterals and the organization and recanalization of the thrombus is one which takes a long period of time. It has been my policy to tell patients who have developed a deep vein thrombosis that it will take them a minimum period of 6 months to recover from it. This may seem like a discouraging statement to the patients but on the other hand it gives them an understanding of the difficult problem of re-establishing circulation. The patients must be made to understand that all during this time the circulation is improving. If they make excessive demands on their circulation by keeping their legs dependent an undue number of consecutive hours the daily recurrent edema may eventually lead to an indurated leg. It is not the number of hours in twenty four which a patient works that may precipitate induration of an edematous leg; it is the number of consecutive hours of dependency. If a patient will interrupt the period of time which he is on his feet by lying down and elevating them, part of the edema will subside and the total edema resulting at the end of the day will be less than if the whole day is spent ambulatory. It is very important for the patient to realize that 'resting the leg' by putting it on another chair when he is sitting down is ineffective and almost inconsequential. The leg is still dependent. If a means of elevating the leg above the heart while he is sitting in a chair can be devised it may do some good. Otherwise he must lie down and elevate the leg above the cardiac level. During the convalescent period immediately following thrombosis it is well to advise patients to interrupt the period of dependency by mid morning rest for a period of an hour and a mid afternoon rest for an hour. This recumbency must be in bed and preferably part at least of that time the affected leg should be elevated. After a period of time when there is less tendency for edema they may have insignificant swelling if they rest only at the mid-day. They should continue these interrupted rest periods for a

to 6 months. If patients carefully follow this regimen even though they have had a severe deep vein thrombosis, the residuals such as pigmentation and hardness in the region of the malleoli will be absent or minimum. In spite of this it is well to caution that if they ever get a laceration or a bruise or infection on that leg they must regard it with a certain amount of seriousness. They must respect it much more than if it occurred on the normal leg. In this way they may prevent trouble. It is much more important for them to go to bed if they have an associated factor such as laceration or bruise than it would be had this injury occurred on the opposite normal leg.

Ulcer resulting from postthrombophlebitic edema is extremely painful and extremely disabling. If it has not been prevented and does occur, the patient will probably have to fight its recurrence even though it responds to therapy and heals promptly. He usually has to combat recurrences the rest of his life. The prevention of it, therefore, is highly important. If it has already occurred various local measures may be employed. It is my experience that ulcers in different individuals though they all be fundamentally postthrombophlebitic ulcers, may respond with great variations to various local measures. Among the agents which might be used are the dyes including gentian violet (2% aqueous solution) scarlet red (ointment) penicillin streptomycin sulfonamides urea zinc peroxide tyrothrycin dried red blood cells zinc oxide bismuth powder Unna paste boots and others. Almost everyone who handles these measures has a favorite. I should like to endorse dried red blood cells which at times are very effective. In addition to that the use of gentian violet in 2 per cent aqueous solution at the same time avoiding soaps and water usually works well. On the other hand it sometimes increases the dermatitis and makes the ulcer spread. Similar ulcers in different patients seem to have no unanimity of response to these local measures.

In addition chemotherapeutic agents systematically such as penicillin and sulfonamides are measures which should not be overlooked. Very frequently a period of bed rest with several spaced procaine lumbar sympathetic

nerve blocks will help to reduce the edema and to obviate the pain of the ulcer and to facilitate its healing.

If postthrombophlebitic ulcers have been long standing or have recurred a number of times and if the area of induration is marked, extensive excision of this whole zone including the bed of the ulcer through the fascial layer and down to the muscles with the replacement of a split thickness skin graft has given us most gratifying results. Our experience with this type of operation has been very satisfying (Figs. 2, 3, 4). In 90 per cent of cases the patients were returned to work and have had no further trouble with ulceration in that area. The freedom from pain is a gift for which they are most appreciative. In addition the deformity resulting from excision of the area is in reality very mild. Usually after a period of time the zone is well graded with the surrounding tissues and the graft is relatively inconspicuous. It is very important to excise the entire indurated area and remove the fascial layer down to the bone or muscle. This seems to give a new base for the skin which so easily ulcerated previous to operation. Undoubtedly the deep circulation now takes care of the blood supply which was so deficient prior to the operation due to scarring. The center of the graft after operation is extremely soft for the base of it is the well vascularized underlying muscle. We usually take out a relatively wide area extending up the leg to the junction of the middle and lower third or to the middle of the leg. We have removed it over the malleoli and down to the sole of the foot. This is an operation which undoubtedly as it is better known will be more widely used for these cases. It may be employed for varicose ulcers as well as postthrombophlebitic ulcers, but it is more frequently indicated in the latter.

Just a word to warn against the ligation of superficial veins when there is a definite history of deep vein thrombosis. If compensatory varicose veins develop in a leg which has been the previous site of a deep vein thrombosis it has been my experience that ligation of them usually does not help the return of circulation and frequently makes it worse. We have had no personal experience in the

transection of deep veins for postthrombophlebitic states as reported by Buxton and Collier. It is hard to read satisfactory results in the reports of these authors. They apparently do not enthusiastically advocate the method. A study of the type which they reported is justified in one or two large medical centers but the procedure should not be used indiscriminately and sporadically until its worth has been proved by reports from several medical centers which acclaim its value.

VARICOSE VEINS

An individual with severe or moderately severe varicose veins should be regarded as a 'prestage' of indurated leg. Adequate treatment should control the retrograde flow of blood in the superficial varicose system. The comparative tourniquet test (Mahorner-Ochsner test) will usually point out the improvement to be expected prior to ligation and segmental resection. When varicose veins are operated upon, the fundamental part of the procedure is a high ligation at the fossa ovalis resection of a small section of the saphenous vein and separate transection and ligation of the adjacent tributaries. In addition to this, if the comparative tourniquet test shows incompetence of the valves of the veins communicating between the deep and superficial systems below that level additional ligations or segmental resections should be done to control most of this back flow. In considering this operation in the light of an indurated leg it may be regarded as preventive surgery. In reality of course there may be other indications for the ligation.

Usually the onset of induration of the leg in a patient with varicose veins is manifested by thrombosis of a small vein in and around the malleolus at the lower end of the saphenous system. In that area edema and hardness appear. The area may become discolored and even pigmented. It may be tender. This should be regarded as a danger phase. External compression and interval rest in the middle of the day will probably help to restrict the spread of induration. If the patient ignores these signs staying ambulatory many hours a day the swelling may recur daily and subcutaneous tissue may become hard in that

area. Eventually fibrosis and scarring with persistent dermatitis, scabiness, and weeping of the skin may result in an ulcer.

When this stage presents itself it is imperative that the varicose veins be ligated in order to improve the circulation and to stop the retrograde flow (Fig. 1). Even if ulceration has supervened, ligation becomes a basis for therapy. As long as the circulation is unpaired with chronic passive congestion of the tissues the pathologic process will progress. Local applications to the ulcer are of much less fundamental importance in the average case. However if a patient has any condition which precludes the advisability of surgery the compression therapy with elastic stocking or temporary Unna paste boot may be accepted. Severe varicose ulcers with induration which persist after ligations should be excised and the area grafted with skin (Fig. 2).

Unless small intracutaneous varicose veins without large rosy varicosities have developed a complication such as thrombosis ligation will probably not improve them sufficiently to justify its being done purely for a cosmetic reason. This statement of course is made in respect to a lower extremity which is the seat of the varicose veins of the small intracutaneous telangiectatic variety only. When they are large dilated saphenous veins or other trunks with marked ectasia the improvement in the circulation may be marked following ligation. Moreover small superficial intracutaneous varicose veins will not respond properly to injections of sclerosing solution. Usually the patient with these is seeking cosmetic improvement. If they are injected with a sclerosing solution it is true the small varicosity may disappear. On the other hand there will be a discolored area leaving a spot which is as cosmetically imperfect as the varicosity. It is my policy to advise patients with small varicosities, who are seeking cosmetic improvement only to let their veins alone.

When varicose veins are moderately severe or severe ligation at the proper level is the treatment of choice. Then improvement in circulation efficiency may be expected. Either varicose veins are severe enough to justify ligation or they are mild and should be left untreated because they cannot be improved

Fig. 1. Varicose ulcer before and after ligation of the saphenous vein. The ulcer healed promptly after the li-

gation. It had been present almost continuously for some 2 years prior to ligation.

cosmetically. If they progress and become more severe ligation can be done at a future date. It seems always fair and even important to tell the patient that whereas varicose veins can be improved by ligation the tendency to develop varicose veins cannot thus be removed. Patients with obesity and superficial varicose veins should be warned against striking their limbs against chairs or other objects. In addition if they have even a minor injury resulting in thrombosis they should be carefully cautioned to interrupt the period of dependency of their legs and elevate them for

an hour or more during the middle of the day until the swelling disappears. Compression therapy in the form of a semielastic bandage (elastoplast or ace bandage) at this period is frequently very helpful. If varicose veins are present and if thrombosis occurs in the varicosities the thrombosis is an additional indication for surgery. When ligations at the proper sites are done for the varicose veins after thrombosis occurs in the varicosities the dual effects of the operation are subsidence of the thrombosis and improvement of the varicosities.

Fig. 2. Varicose ulcer before and after excision and skin graft. The patient's varicose vein had previously been ligated but prior to ligation the indurated area had been present so long and so much scarring was present that she was not able to prevent the skin from repeatedly breaking open and ulcerating. Following excision and skin graft she has remained well for over a year in spite of the fact that she is a nurse.

transection of deep veins for postthrombophlebotic states as reported by Buxton and Collier. It is hard to read satisfactory results in the reports of these authors. They apparently do not enthusiastically advocate the method. A study of the type which they reported is justified in one or two large medical centers but the procedure should not be used indiscriminately and sporadically until its worth has been proved by reports from several medical centers which acclaim its value.

VARICOSE VEINS

An individual with severe or moderately severe varicose veins should be regarded as a prestige of indurated leg. Adequate treatment should control the retrograde flow of blood in the superficial varicose system. The comparative tourniquet test (Mahorner-Ochsner test) will usually point out the improvement to be expected prior to ligation and segmental resection. When varicose veins are operated upon the fundamental part of the procedure is a high ligation at the fossa ovalis, resection of a small section of the saphenous vein and separate transection and ligation of the adjacent tributaries. In addition to this, if the comparative tourniquet test shows incompetence of the valves of the veins communicating between the deep and superficial systems below that level additional ligations or segmental resections should be done to control most of this back flow. In considering this operation in the light of an indurated leg it may be regarded as preventive surgery. In reality of course there may be other indications for the ligation.

Usually the onset of induration of the leg in a patient with varicose veins is manifested by thrombosis of a small vein in and around the malleolus at the lower end of the saphenous system. In that area edema and hardness appear. The area may become discolored and even pigmented. It may be tender. This should be regarded as a danger phase. External compression and interval rest in the middle of the day will probably help to restrict the spread of induration. If the patient ignores these signs staying ambulatory many hours a day the swelling may recur daily and subcutaneous tissue may become hard in that

area. Eventually fibrosis and scarring with persistent dermatitis, scaliness, and weeping of the skin may result in an ulcer.

When this stage presents itself it is imperative that the varicose veins be ligated in order to improve the circulation and to stop the retrograde flow (Fig. 1). Even if ulceration has supervened ligation becomes a basis for therapy. As long as the circulation is impaired with chronic passive congestion of the tissues the pathologic process will progress. Local applications to the ulcer are of much less fundamental importance in the average case. However if a patient has any condition which precludes the advisability of surgery the compression therapy with elastic stocking or temporary Unna paste boot may be accepted. Severe varicose ulcers with induration which persist after ligations should be excised and the area grafted with skin (Fig. 2).

Unless small intracutaneous varicose veins without large rosy varicosities have developed a complication such as thrombosis, ligation will probably not improve them sufficiently to justify its being done purely for a cosmetic reason. This statement of course, is made in respect to a lower extremity which is the seat of the varicose veins of the small intracutaneous telangiectatic variety only. When they are large dilated saphenous veins or other trunks with marked ectasia the improvement in the circulation may be marked following ligation. Moreover small superficial intracutaneous varicose veins will not respond properly to injections of sclerosing solution. Usually the patient with these is seeking cosmetic improvement. If they are injected with a sclerosing solution it is true the small varicosity may disappear. On the other hand there will be a discolored area leaving a spot which is as cosmetically imperfect as the varicosity. It is my policy to advise patients with small varicosities, who are seeking cosmetic improvement only to let their veins alone.

When varicose veins are moderately severe or severe ligation at the proper level is the treatment of choice. Then improvement in circulation efficiency may be expected. Either varicose veins are severe enough to justify ligation or they are mild and should be left untreated because they cannot be improved

Fig. 1. Varicose ulcer before and after ligation of the saphenous veins. The ulcer healed promptly after the li-

gation. It had been present almost continuously for some 12 years prior to ligation.

cosmetically. If they progress and become more severe ligation can be done at a future date. It seems always fair and even important to tell the patient that whereas varicose veins can be improved by ligation the tendency to develop varicose veins cannot thus be removed. Patients with obesity and superficial varicose veins should be warned against striking their limbs against chairs or other objects. In addition if they have even a minor injury resulting in thrombosis they should be carefully cautioned to interrupt the period of dependency of their legs and elevate them for

an hour or more during the middle of the day until the swelling disappears. Compression therapy in the form of a semielastic bandage (elastoplast or ace bandage) at this period is frequently very helpful. If varicose veins are present and if thrombosis occurs in the varicosities the thrombosis is an additional indication for surgery. When ligations at the proper sites are done for the varicose veins after thrombosis occurs in the varicosities the dual effects of the operation are subsidence of the thrombosis and improvement of the varicosities.

Fig. 2. Varicose ulcer before and after excision and skin graft. The patient's varicose veins had previously been ligated but prior to ligation the indurated area had been present so long and so much scarring was present that she was not able to prevent the skin from repeatedly breaking open and ulcerating. Following excision and skin graft she has remained well for over 1 year in spite of the fact that she is very active.

Fig. 3. An ulcer of the leg before and after excision and graft. The main etiologic factors here are obesity and trauma. She previously had minor intracutaneous aneurysms injected. The ulcer had been present for period of 5 years. After excision of the indurated area down through the fascial layer and application of the split thickness skin graft this patient has remained well. She is very thin. The center of the grafted area is quite soft since underlying the skin there is muscle. This affords good vascularity in the surrounding area.

OBESITY

Obesity is a frequent factor in the development of indurated leg (Fig. 3). It is rarely of itself the only factor. Combined with trauma, thrombosis, infection, lymph stasis, or systemic causes of passive congestion such as cardiac disease, it may exert its effect in such a manner as to increase edema and bring about fibrosis of the subcutaneous tissue. Patients who are obese have a tendency to thrombosis. If they have varicose veins, they should be cautioned about the dangers of even slight trauma which might precipitate a thrombosis and lead to induration. In addition, localized infections such as furuncles on the lower extremity in the obese patient should be respected as conditions much more likely to lead to chronic trouble than if the same process occurred in a patient of normal weight. Once established, erysipieloid with its recurrent infection and high fever has a fertile soil in the obese leg. These repeated infections lead to chronic swelling and eventually to thickening of the subcutaneous tissue.

The preventive treatment of indurated leg as far as this factor is concerned involves the prevention of obesity with all of its difficulties. In addition to that, it involves the prevention of other associated factors such as injury or long continued dependency which might in-

crease the tendency of the intracellular fluid to become static and pool in and around an obese ankle. Whenever an obese patient develops the slightest additional complication such as a small thrombosis in the vein of a lower extremity, he should be cautioned to treat the condition as if it were something potentially very serious. Compression therapy and bed rest may help it to resolve and prevent it from becoming chronic.

TRAUMA

Trauma may be the incipient cause of indurated legs in several different ways (Fig. 4). Even slight blows to the subcutaneous tissue, particularly around the internal malleolus, may result in edema. Apparently at times this edema of the subcutaneous tissue and overlying skin is not attended by any thrombosis in the veins. There is undoubtedly a vascular disturbance which may be so severe that vasospasm of the veins and arteries of that extremity is a decided factor in the persistence of edema.

One frequently hears the story of a patient aged 50 that some 15 or 20 years ago struck his leg on a sharp corner of a rocker. It hurt and was annoying at the time but the patient was very busy and had to continue working for many hours a day. The swelling continued day after day. He felt that it should disappear spontaneously. Perhaps he did not even go to a physician, but if he did he probably did not foresee the ultimate end result, namely, an indurated leg and ulcer. To prevent induration of the leg from such causes, the patient should respect the possibility that the effects of the injury may become chronic. He should rest in the middle of the day with the leg elevated and should use compression bandages of the ace type, or if the trauma has been severe enough, he should remain recumbent most of the time for a period of a few days.

Another type of trauma which results some times in an indurated leg is that from a more severe injury such as a fractured femur or a fracture of the tibia. Hardness and induration of the subcutaneous tissue around the malleoli are commonly seen as sequelae of these injuries. There are probably two different pathogenic

onsets for induration resulting from such trauma. One is that which accrues from injury to the deep vein with thrombosis at the time of the fracture. Because the patient was lying in the bed with the limb elevated the immediate consequences of this thrombosis of a large collecting vein may have been overshadowed by the objective evidence of the fracture itself. Only in the convalescent period after union when the patient was becoming rehabilitated was it noticed that the leg swelled inordinately.

Injury to the lymphatics and smaller veins in the region of the ankle attending the fracture of the tibia may cause considerable chronic disturbance in the circulation and tendency to subcutaneous edema persisting long into the convalescent period. Interrupted dependency and external compression bandage during this phase is very very important. All of these injuries are attended with vascular disturbances with vasospasm. Even minor injuries may have a posttraumatic syndrome equivalent to Sudeck's atrophy with edema and eventually with atrophy of bone and persistence of the pain.

The active treatment of the edema which results from trauma is rest and elevation either constant or interrupted whichever may be necessary. As a supplementary measure external compression is very valuable. Sometimes temporary interruption of the sympathetic nervous impulses by procaine lumbar sympathetic nerve blocks is of great value. Careful judgment should be used in selecting different measures but in all instances great respect should be exercised when edema is occurring day after day. If it does so and does not abate indurated leg is inevitable.

INFECTION

Infection has been mentioned a number of times as a partial factor operating with other factors in the production of indurated leg. One should recall to mind the tissue vitality of the skin of the leg. It is relatively very poor. Any infection there resulting from an open wound or furuncle is apt to heal very slowly. Resolution takes much more time and an important part of the preventive and active treatment of such lesions is to regard them as being

Fig. 4-11. Resultant of excision and skin graft of an ulcer of the leg, which according to the history followed a bruise to the leg in the region of the ankle. Apparently trauma had been a major factor in this ulceration. No preoperative photograph is available but the ulceration was extremely painful. This patient, aged 36 years, is an active business woman. Since her graft in July 1946 she has remained well.

potentially more dangerous and more likely to develop into chronic stages than are similar lesions elsewhere on the skin of the body.

Infection in the skin in the form of a recurrent erysipieloid or erysipelas is an extremely dangerous extremely disabling illness. The attacks tend to recur after a period in which the host has been very active. Practically all of the attacks begin at one spot. The patient describes an itching sensation and then usually an onset of a chill with high fever. Within a few hours the leg is intensely red and very painful and the patient is extremely sick. The repetition of the infection over and over again results ultimately in much hardness of the leg skin and subcutaneous tissue and sometimes in ulceration. We have used sulfonamides, penicillin and other measures in an effort to prevent the attacks. None of these measures have worked entirely satisfactorily. In one instance in a young man who was having recurrent attacks of erysipieloid I excised the trigger area. We studied carefully the onset of the trouble. Each attack seemed to begin around the malleolus. The following is his history:

M. S., a young man aged 19 years, came under our care on August 2, 1946. For 6 years he had attacks of chills and fever accompanying painful swelling of the left foot and leg. The last attack had

Fig. 5. Congenital lymphedema in an old child. There is no pathosis of the dorsum of the left foot and slight increase in size of the left leg. The middle of the calf. The ulcerous tissue on the dorsum of the left foot, including the fascia, was excised through the erected staple-shaped incision. This patient died prior to operation but has been observed now for period of 4 years. The result is excellent. A slight thickening of the left leg persists. Since congenital lymphedema often leads to subsequent attacks of erysipelas, conditions such as this should be treated surgically early in life. The photograph shows the legs preoperatively and 20 months after operation. (11 January 1948 this patient now aged 9 years, had first attack of erysipelas induced by epidermophytosis.)

been in June 1946. The condition broke all together like a recurrent erysipelas. Examination at the time was first seen revealed negative findings except for slight thickening of the subcutaneous tissue in the lower half of the left leg from just above the ankle. It was asked at this time just where the first signs of the infection appeared. He was not certain but he thought that the attack began in the region of the ankle. He was sent home advised to take 500,000 units doses of penicillin once a week for a period of 6 weeks. On December 4, 1946 he returned again from his home in another state. He had had a bilateral attack. At this time it was observed by him in the recent attack that they always began in the region of the internal malleolus.

It was decided then to excise a area of skin about 10 cm. in diameter and fascia zone in which the attack was thought to begin. On December 4, 1946 this was done. A split thickness skin graft was taken from the right thigh and was placed on the internal malleolus. In addition in order to improve the circulation to the lower extremity a left lumbar sympathectomy was performed December 20, 1946. A report from the patient received 1 November 1947 states that he has had no attack of erysipelas since the operation except for mild one in September 1947 which was initiated after excessive exercise. He attended in person at the time that he is likely to be in an excellent condition.

We felt that the etiology of this man's condition was an acquired lymphedema. Whether

the lymphedema followed the erysipelas or whether it was a primary factor with a superimposed recurrent infection we were not able to determine from the history. There is no familial history of lymphedema in his case.

In addition to the bacterial types of infection which may be factors in the development of the indurated leg, one should consider trichophytosis as a common secondary invader to a chronically edematous skin. It is not easy to prove this each time by laboratory methods. On the other hand it has been proved that fungus of this type may affect the skin. It usually does so in the region of the internal malleolus. It is necessary to combat onychomycosis and trichophytosis of the feet in patients with recurrent or persistent swelling of the leg and with a scaly dermatitis of the malleolar region. In a very warm climate one gains the impression that this fungus is very widespread and very common. It is abetted by moisture and in its presence soaps and water seem to enhance the pathologic process. Apparently at times the fungus infection of the trichophyton variety may be the initial and only cause of the leg ulcer. It is true that without other complications this lesion may fall into the category of dermatology but one handling leg ulcers cannot help being impressed with fungus invasion as a factor in the development of leg ulcers.

LYMPHEDEMA

Lymphedema may be familial or it may be sporadic; it may be acquired later in life or it may be congenital. If it is seen early in life and there is a family history of it it may be termed Milroy's disease or Nonne-Milroy disease. If there is a family history of it and if it presents itself at puberty, it may be regarded as Meigs's disease. Moreover it may be secondary—the result of obstruction of major lymphatic channels from repeated infection or by parasitic invasion, namely filaria.

The condition may be a diffuse thickening of the subcutaneous tissue of the leg or it may be localized subcutaneous deposit with ectatic lymphatics, fat and fibrosis. If it is observed early in life the tendency for it is to advance, spread and become more severe as the child grows older. Many of these patients have

very little trouble from it. It is much more common than is usually appreciated and with out complications it may interfere little with a very active life. On the other hand it is fertile soil for infections.

Measures to prevent a leg which is the seat of lymphedema from becoming indurated involves an effort to avoid all associated factors. When any complications appear they should be treated cautiously and with full knowledge that they may change the process into one which could be very disabling. Should induration and ulceration appear the active treatment may mean excision by a Kondoleon type of operation. Even before ulceration excision particularly of localized lymphedematous masses may be indicated.

I believe that when localized sporadic lymphedema is present and seen early in life it should be excised. The following is a brief abstract of such a case.

The child (F P) aged 2 years when first seen had a marked swelling on the dorsum of the left foot. It had been present since birth. The swelling seemed to be increasing in size and because of it a shoe could not be worn on that foot. The swelling was soft was never painful.

When examined the patient showed a diffuse soft swelling of the foot involving the dorsum and extending to the ankle. It was about 2 centimeters thick in its greatest depth and was about 6 by 6 centimeters in the other dimensions. In addition to that the left leg was slightly larger in circumference than the right. The subcutaneous tissue was thicker than normal but not hard. The condition was regarded as congenital lymphedema. The child was kept under observation for 1 year. Then an operation was performed.

Through a horseshoe incision elevating the skin the whole zone of thickened subcutaneous tissue was excised including the fascia. The skin was then replaced. The wound healed promptly and the child has made an uneventful recovery. She has developed normally. She has been observed at intervals for 5 years since the operation. The result is excellent (Fig 5). Pathologic examination of the section removed revealed fat dilated lymphatic spaces and fibrous tissue.

The onset of recurrent erysipelas in a patient with lymphedema of the lower extremity leads to a very serious point in judgment. When lymphedema is severe a Kondoleon type of operation may be of great advantage in relieving the enormous swelling. If the trigger zone could be excised at the same time the

Fig 6. Immersion leg. Chronic swelling and thickening of the subcutaneous tissue with ulceration of the leg which was initiated after this officer had to lie immersed in water for a period of 30 hours during an invasion. This condition was treated conservatively mainly by restricted activity. Since returning to civil life he had been very active and consequently had daily recurring edema of the lower extremities. Impaired circulation such as this will not withstand many consecutive hours of dependency.

recurrence of the attacks may be obviated. I believe that if these patients can be seen soon after the onset of recurrent erysipelas some effort should be made to excise the zone in which the infection lies dormant during remissions. We have tried giving patients various chemotherapeutic measures to reduce the number of attacks or to obviate them. Usually it is not successful but in a few instances we have seen apparently what amounts to a cure that is cessation of the attacks of infection in the leg with fever. I have seen patients who I thought were better off to have an amputation because of continued disability from recurrent erysipelas than to try to keep the lower extremity. Usually when told this they are very reluctant even though they have spent many months out of the last year convalescing from an attack.

IMMERSION LEG

The name immersion leg is intended to designate chronic edema of the leg which results after the trunk or lower extremities have been immersed in water for many hours or days. This injury resulted many times during war when boats were torpedoed and survivors were picked up after they had been immersed in

Fig. 7

Fig. 8

Fig. 7 Leg ulcer partially the result of an indirect trauma. The patient had 5 years had funnel chest with displacement of the heart and interference with respiration resulting chronic edema of the legs which he said as present prior to the operation.

Fig. 8 Postoperative view of patient shown in Figure 7. He felt better than he ever had before and now weighs 150 pounds more than he ever weighed before. The ulcers present on each leg have healed and have not recurred since the operation.

water for many hours. The following brief history is typical of these cases:

Carlton H. aged 47 years with a history of the following: He complained of swelling of the legs for 36 hours before he was lying half in the water and half out. The temperature at the time was normal. Ever since then his legs have been swelling. After his return to civil life he has a small ulcer on the right leg. This requires him to work many hours a day in some heat and when he lies so the swelling is pronounced. Recently an ulcer has appeared near the distal malleolus of the right leg. Examination revealed tremendous swelling and induration of both legs below the middle of the thighs (Fig. 6). A small leg ulcer was present near the right external malleolus. Thorough investigation revealed that he did not have filaria. A scaly dermatitis was found on both legs above the ankles suggesting a fungus infestation of the skin. A condition he himself termed "jugular rot." The treatment advocated was conservative with more restriction of activity.

The cause of recurrent edema after immersion in water is obscure. Apparently the ves-

sels lose their tone and the tissues are damaged so that intercellular spaces remain open and subject to ready filling.

ARTERIOVENOUS COMMUNICATIONS

Any condition in which the arterial blood is emptied directly into the larger veins may lead to edema and eventually to induration and ulceration. Arteriovenous communications are mentioned to make the classification comprehensive. If the lesion is congenital or occurs early in life from trauma the lower extremity is likely to be longer and larger than the opposite. The diagnosis when an arteriovenous communication is large enough to result in edema should be more or less obvious. If induration alone is the symptom presented, diagnosis of arteriovenous communication will not be overlooked if it is remembered as a possible cause. The proper treatment is surgical attack on the arteriovenous communication.

SYSTEMIC CAUSES

It is surprising sometimes to find the cause of an indurated leg far removed anatomically and even physiologically. I have seen a patient whose chief complaint was indurated leg, and leg ulcer and the fundamental cause behind this predominant problem was a nodular goiter with hyperthyroidism. The patient had been having mild cardiac decompensation with edema of the legs. The edema had resulted in induration in the region of the internal malleolus and ulceration supervened. Even more interesting was a patient sent because of leg ulcers. His history is as follows:

J. M. aged 25 years developed an ulcer on the right leg 10 years ago. Several injections were given in the veins and the ulcer healed. Since that time ulcers have developed on both legs in the region of both the internal and external malleoli. His legs swell almost daily. From birth he had a marked depression in the center of his chest.

Examination revealed a tall young looking man. He had a most pronounced funnel chest. There was extreme depression of the sternum at the lower end. In addition to this he had leg ulcers on both legs near the internal malleoli and pigmented indurated areas near the external malleoli which had been previous sites of ulceration (Fig. 7). Careful studies were done on this patient which will not be reported in detail here. We estimated that his circulation was deficient, partially due to the marked displacement of his heart to the left and possibly also due to pressure on the inferior vena cava by the retrodisplacement of the lower end of the sternum. On July 2, 1947 he was operated on for the funnel chest. The lower portion of the sternum was removed and after reshaping it, it was replaced so that the defect was obviated. During his convalescence there was considerable drainage from the wound and infection supervened. We thought it was necessary to take out the graft which consisted of the lower end of the sternum and the adjacent cartilages. The wound healed. The ulcers in the meantime healed entirely. He was seen again in January 1948. The circulatory efficiency had improved remarkably. He weighed 10 pounds more than his previous maximum weight (Fig. 8). He felt better than he had ever felt. His venous pressures were lower than preoperative levels and were identical in leg and arm veins. Prior to operation the pressure in the leg veins at cardiac level was higher than that of the arm veins. The ulcers had healed following operation and ankle edema had disappeared. In January 1948 he had a recurrence of 2 ulcers on the right foot and ankle which appeared to be due to trichophyton. Edema of that ankle only was noted at that time.

Various other distant causes may be factors in the production of induration and ulceration

Fig. 9. Severe ulceration and induration of the leg. This is a neglected case of leg ulcer which has multiple causal factors including varicose veins and obesity. The subcutaneous tissue is thickened and very hard. Amputation is among the measures to be seriously considered for this degree of disability.

of the leg by interference with return circulation. For example cirrhosis and ascites and pelvic tumors which press on the iliac veins may initiate chronic passive congestion. In addition to this systemic factors such as diabetes and arteriosclerosis may be causal components in the development of leg ulcer and induration. These lesions rarely are the sole cause of leg ulcers but they may be a contributing cause and in order to heal the ulcer and prevent its recurrence all factors should be obviated as far as possible. Sickle cell anemia may be responsible for leg ulcer. Usually in this and some other systemic condition such as tuberculosis ulceration appears first and induration is a secondary accompaniment. Syphilis is frequently a cause of leg ulcer and if it persists over a long period of time marked induration may result. Filariasis is a systemic parasitic infestation with localized lymphatic obstruction is not to be forgotten as a possible cause of acquired lymphedema.

SUMMARY

A clinical viewpoint involving the classification of indurated leg and leg ulcers based on the etiology is given. These conditions should be regarded as chronic progressive processes. Various factors are usually responsible for any induration of the leg and leg ulcer. It is im-

portant in the management of these conditions to attempt to obviate each and every factor. The treatment is preventive and active. Preventive treatment usually involves a respect for the seriousness of daily recurring edema of the leg. Various measures to be used in prevention and active treatment were mentioned. Some indications as to judgment and selection of different measures were discussed. Emphasis was repeatedly placed on the importance of preventing the recurrence of swelling in the leg day after day. This is a predisposing factor to indurated leg and the patient should be warned of its potential seriousness.

A great deal can be done not only to prevent these conditions but also to control them and at times to cure them. Several individual cases were cited to illustrate the selection of surgical measures for some of these problems.

If a patient is entirely incapacitated because of an indurated and ulcerated leg and if the prospect of cure of the ulcer is poor amputation should be considered. Usually patients are repelled by such a suggestion but the truth of the matter is that they would be better off living without a leg than living only for it.

BRONCHIOGENIC CARCINOMA

WITHIN a period of 35 years primary carcinoma of the lung has advanced from a position of obscurity as a rare curiosity to one of great frequency. There is even some evidence now to indicate that it has displaced carcinoma of the stomach as the most common visceral cancer. Statistical studies at the St. Louis City Hospital and at the Charity Hospital in New Orleans (Ochsner and DeBakey¹) have shown that actually primary carcinoma of the lung is more frequent than that of the stomach. This finding is of particular significance because these hospitals represent a cross section of the population of those two cities although at a lower economic level.

Because of its frequency it is important that great emphasis be placed on the desirability of early diagnosis and on the now well established fact that it is no longer an incurable or hopeless condition if the proper treatment is instituted at a sufficiently early time.

In regard to the diagnosis certain points should be stressed. It is primarily a disease of males (about 6 males to 1 female) during or after middle age. Since primary cancer of the lung practically always if not always arises in a bronchus the most common symptom is cough. In more than half of the cases the sputum sooner or later becomes characterized by streaks of blood. These two features are more pronounced if the cancer has arisen in a major bronchus. Unfortunately when it arises in a small bronchus at some distance from the main stem bronchus of either the lung or of any of the lobes both cough and bloody sputum may be absent. Such patients often have no warning of symptoms until the condition is too far advanced to be curable. As in other forms of cancer pain and loss of weight are usually late symptoms and often denote incurability. It cannot be stressed too emphatically that a middle aged man with an unexplained cough and bloodstreaked sputum should be strongly suspected of having a bronchiogenic carcinoma and that steps should be undertaken at once to make the appropriate examinations.

Of the methods of examination the most important are the x ray, bronchoscopy and the newer procedure of examining the sputum or bronchial secretions for cancer cells.² Even with a combination of these methods a definite diagnosis can be made in only about 85 per cent of cases. In the remaining 15 per cent it is necessary to perform an exploratory operation. Experience has shown, however, that in practically 100 per cent of cases when both the history and examinations are suspicious

¹Ochsner A., and DeBakey M. *Surgery* 1940, 8:993.

²Wandall, H. *na. Study on Neoplastic Cells in Sputum*. Copenhagen, Arnold Busck, 1944.

the tentative diagnosis of bronchiogenic carcinoma is found to be correct at the exploratory operation. It is dangerous in such cases to subject the patient to a period of observation waiting for the diagnosis to be established. Many curable cases are converted into incurable ones by such a procedure.

There was no successful treatment of this condition until 1933.¹ In April of that year the author of this editorial had the opportunity of performing the first successful one stage removal of a lung in a patient who had a squamous cell bronchiogenic carcinoma arising in the main bronchus of the left upper lobe. The patient is still living and well more than fifteen years later. Since that time the operation of total pneumonectomy has become the standard treatment for bronchiogenic carcinoma throughout the world. This procedure follows the rule of the surgical treatment of cancer of other organs in that a higher percentage of 5 year cures can be obtained if the whole organ rather than only a part is removed. It has the additional advantage over a mere lobectomy in that it makes possible the removal of more regional lymphatics.

During the fifteen years that have elapsed since the first successful one-stage pneumonectomy much has been learned about the curability of this otherwise hopeless condition as well as the limitations of the operation. Also of course the technical aspects of the procedure have been greatly improved (Rienhoff² and Crafoord³). Likewise as experience has accumulated much has been learned also about bronchiogenic carcinoma itself although the etiological factors and why the condition is chiefly one of the male sex remain obscure.^{4,5}

Our own experience at the Barnes Hospital is based on a series of 1117 cases of proven bronchiogenic carcinoma from July 1, 1920, up to July 1, 1948. Since the first case of successful one-stage pneumonectomy on April 5, 1933 we have performed 296 operations of that sort of which 184 have been for malignant tumors. One of the most distressing features of the problem is the relatively small number of patients who present themselves with a cancer early enough to permit the removal of the lung. In our cases only about 25 per cent have had a pneumonectomy. We have probably been more conservative in this respect than some other surgeons. Space is too limited to permit here a discussion of this point except to say that we have not been convinced of the wisdom of going ahead with the removal of the lung when it is obvious that cancer tissue will be left behind. The chief deterrent factor however is usually the finding in those patients in whom exploratory operation has been done of invasion of the hilar vessels by the cancer, a condition which would make the operation not only excessively dangerous but futile as well. In a recent series of 260 cases we performed a pneumonectomy in 22.3 per cent. In an additional 32 per cent we carried out an exploratory operation but found the cancer too far advanced in our opinion for a resection of the lung. In the remaining approximately 45 per cent an operation was not performed because either the condition was obviously hopeless or other features seemed to preclude the chance of a successful operation such as advanced age or general poor condition.

Two questions of paramount importance are, of course, the immediate operative risk and the chance of a five year cure. It is gratifying that the operative mortality has steadily declined until now it is very respectable. In the early years it was 53 per cent but last

year (1947) of 39 pneumonectomies for cancer we had only 2 deaths a hospital mortality therefore of only 5.1 per cent. Those who are more radical in their attempts at resection will have a higher operative mortality.

As regards late results there is reason to be optimistic. Of our own series of 53 patients who had pneumonectomies prior to 1942, 15 are alive and well. This is a five year survival rate of 28 per cent. The next five year period will undoubtedly show better results because of the sharp reduction in operative mortality. After all, in the early years 53 per cent or 28 patients died of the operation and there was no chance therefore to determine how many of that number might have lived more than 5 years if they had survived the operation. This is to be contrasted with the present operative mortality of 5 per cent. Of the five year survivors in our series the highest percentage was in the malignant mixed tumors (57 per cent of 16 patients). In 22 cases of squamous carcinoma 3 patients (14 per cent) are alive 5 years later and in 15 cases of undifferentiated carcinoma 3 patients (20 per cent) are alive after 5 years. In those cases with invaded lymph nodes naturally the results are not so good. Yet some are still living. Of 5 patients who had pneumonectomies for malignant mixed tumor with node invasion 2 are alive more than 5 years as is 1 patient of 12 with squamous carcinoma and lymph node invasion. Obviously, as is true with cancer in general, the earlier the lesion the better the result, but involvement of regional lymph nodes does not make the prognosis completely bad.

In summary, one may say that bronchiogenic carcinoma is now recognized to be one of the most frequent forms of cancer. The operation of total pneumonectomy offers hope to those victims of this disease who prior to 1913 had no hope. Nowadays the principal problem in improving the results is to have

patients come for help early enough to permit the operation. This means education of the profession to the recognition of the frequency of this condition, the necessity of early examinations of a proper kind, and the fact that the early case is curable.

EVARTS A. GRAHAM

MEDIASTINAL TUMORS

MEDIASTINAL tumors are relatively rare lesions. It is safe to predict, however, that the practice of making routine roentgenologic examination of the chest will establish the fact that mediastinal neoplasms are much more common than past experience would indicate. Bronchiogenic carcinoma was regarded as a rare disease years ago but it is now known to be one of the most common forms of cancer. These facts suggest that other intrathoracic tumors may be of more importance than has been attributed to them in the past.

Accumulated data from Army experiences during the past war are not yet available. It is significant, however, that 109 patients were operated upon for mediastinal tumors at Army thoracic surgery centers in the United States during a period of approximately three years. This series did not include cases of mediastinal neoplasms of lymphatic origin such as lymphosarcoma, mediastinal Hodgkin's disease and similar conditions. It is of particular significance that in 94 of the 109 cases no clinical manifestations of intrathoracic disease were present; the tumor was found on routine roentgenographic examination.

Successful treatment of mediastinal tumors depends on their detection before clinical signs are apparent. Block excision as used in carcinoma of the breast, skin, and elsewhere is precluded because of the anatomic arrangement of the mediastinum. Successful surgical

therapy therefore, is impossible unless the lesion is localized and encapsulated.

In the past there was a tendency to 'watch asymptomatic mediastinal masses. This policy for intrathoracic tumors was understandable when the risk of exploratory thoracotomy was considerable. It can be stated categorically however that at the present time the danger of exploration of the mediastinum is trivial provided the patient is in reasonably good condition and provided qualified anesthesiologists and surgeons are available.

The discovery of a mediastinal mass by routine roentgenologic examination with or without associated clinical manifestations demands positive diagnosis. Should no available diagnostic procedure provide an infallible method to determine preoperatively the exact nature of a mediastinal tumor only two therapeutic methods are available: radiation therapy and surgical extirpation. With few exceptions the only mediastinal tumor which will respond to radiation therapy is one of lymphatic origin (lymphosarcoma, Hodgkin's disease and others.)

Radiologists and surgeons experienced in thoracic disease should be able to predict, in the majority of cases, from roentgenographic and clinical evidence the presence of a lymphoma. These tumors have a tendency to produce clinical symptoms early and their appearance on the roentgenogram is rather characteristic. Properly employed radiation therapy is invaluable both as a therapeutic and diagnostic measure if a tumor of lymphatic origin is suspected. Disaster may be anticipated however if injudicious radiation is employed in all cases of mediastinal tumors.

The mediastinum may harbor almost any type of tumor. For practical purposes it is convenient to classify common mediastinal tumors in two varieties: anterior mediastinal tumors and posterior mediastinal tumors.

The most common anterior mediastinal tumor is a neoplasm of lymphatic origin. Lymphosarcomas, Hodgkin's disease, granulomas, and other lymphatic tumors usually have a characteristic pattern which would indicate the administration of a test dose of radiation therapy. It should be emphasized however that about one third of the malignant lymphomas are slow in their reaction to radiation. If after a period of approximately one month of adequate radiation therapy there is no change, thoracic exploration should be performed to determine the exact nature of the lesion.

Dermoid cysts and teratomas of the mediastinum are the second most common neoplasms situated in the anterior mediastinum. In discussing these neoplasms Harrington^{1, 2} simplified the terminology by employing the inclusive term 'teratoid tumors.'

The chief source of confusions in the diagnosis of anterior mediastinal tumors is the differentiation between lymphatic tumors, teratoid tumors, thymomas and bronchiogenic cysts. When academic pride is excluded there remains only the choice between the lymphoma group and all the others. If any doubt exists thoracic exploration should be performed to establish a positive diagnosis.

Posterior mediastinal tumors are chiefly of one common variety. Neoplasms of neurogenic origin are by far the most common. Kent³ and his co-workers collected 105 cases in the medical literature. 59 cases were recorded in my Army experience.⁴

The incidence of primary nerve tumors of the mediastinum is unknown. Most of these lesions are found on routine roentgenologic examination and are asymptomatic. Occasionally nerve involvement may cause pain if

⁴Blades, Brian. Ann. Surg., 940, 23, 740.

the sympathetic chain is involved Horner's syndrome may be evident Too often however definite clinical signs of disease indicate the presence of malignant degeneration and inoperability

Once considered rare bronchiogenic cysts are now known to be fairly common Laipply¹ reported 35 cases in 1945 In a period of three years 23 mediastinal bronchogenic cysts were removed in Army hospitals These cases were all found on routine x ray examination Pericardial cysts may occur Thymomas are relatively rare These tumors are usually located in the anterior mediastinum in a substernal position However bronchogenic cysts lymphomas and thymomas may occur in either the anterior or posterior position

Other varieties of mediastinal tumors include fibromas (probably neurofibromas) tumors of thyroid origin tuberculomas cysts of the esophagus osteochondromas and other

unusual neoplasms Enlarged lymph nodes Boeck's sarcoid and aneurysms can be mistaken for mediastinal tumors

Until precise diagnostic methods are available therapeutic measures in the treatment of mediastinal tumors will remain limited to radiation therapy and surgical removal Tumors which respond to roentgen therapy are usually incurable others may be amenable to surgical extirpation

The choice between radiation therapy and surgical intervention will depend first upon the tentative diagnosis and second upon the danger of exploratory thoracotomy If roentgenologic and clinical evidence indicate the presence of a lymphoma a test dose of radiation should be given If improvement does not follow in due course thoracic exploration should be carried out unless the general condition of the patient precludes the use of any type of surgical intervention

THE BOOK SHELF

JOHN COAKLEY LETTSOM AND HIS LITERARY FRIENDS

JOSIAH C TRENT M.D. F.A.C.S. Durham, North Carolina

On Wednesday May 15, 1776 James Boswell, busy with his microscopic examination of the opinions, character and behavior of the great Dr Johnson subjected his hero to a test. He arranged for a dinner at the house of Edward and Charles Dilly the booksellers. The other guests, not named to Johnson until he met them in Dilly's drawing room, included the radical John Wilkes, regarded by Johnson as not only for hanging, and Arthur Lee who to quote Boswell, "could not but be very obnoxious to Johnson for he was not only a patriot but an American." On being introduced into this uncongenial company Johnson gave vent to a few resentful "tut, tut, tut's," stepped aside from the group, and fixed his attention on a book he had taken up. With the call to dinner he rejoined the others, his composure restored. Wilkes' assiduity in helping him to choose bits of veal changed composure into complacency and Johnson was soon in a mood to enjoy fully both dinner and table talk.

Boswell's account of this momentous occasion is chiefly concerned with the conversation of Johnson, Wilkes, Lee, and himself on such subjects as actors, poetry, and Scotland. The other guests present are mentioned only once "Mr (now Sir John) Miller Dr Lettsom and Mr Slater the druggist." With two of these gentlemen we are no more concerned than Boswell was, but Dr Lettsom deserves a closer examination.

Since 1770, John Coakley Lettsom had practiced medicine in London, with notable success. A Quaker born in the West Indies in 1744 he had been educated in a school near Lancaster then apprenticed for five years to a surgeon and apothecary in Settle, Yorkshire. His medical education had been completed by a year in the London hospitals, and, after six months of practice

in the West Indies to recruit his finances, by courses of study at Edinburgh and Leyden. He graduated M.D. at the latter university on June 20, 1769 with a thesis on tea. The young author suggests in this essay with the authority possible only to the medical student, that the universal use of tea has been responsible over several generations, for a noticeable decrease in the strength of the human constitution and for a consequent decrease in the frequency of violent fevers.

"This change and diminution of inflammatory diseases, however brought about, tho' it may free us from the attacks of many violent symptoms, is nevertheless productive of more pernicious effects, and more troublesome complaints, than the former, both with respect to number & degree of violence. A multitude of Diseases, & complicated ailments have succeeded, to which our ancestors were strangers. Our Bodies be lost that strength, & admire in our ancestors, and become enervated, and liable to more diseases: and those depending upon relaxation and debility are now endemic. Hence that frequency of Hysterics in both Sexes, the Hypochondriacs, Palsy, Cachexy Dropsy &c.

"It is thus that what has been advanced, I would by no means conclude that Tea is the sole cause of all these complaints for hurry of every kind, to please the palate, has almost every where extended its influence & even entered our Kitchens and Cellars, and contributed its share in the production of those diseases with which labor Under this head the frequent use of spirituous liquors stands foremost.

But why does this custom so frequently occur? The answer is obvious. The economy of the whole frame rendered call & feeble by the constant and daily use of drinking Tea, and being sensible of debility and oppression, leads the trembling hand, to seek temporary relief, in some cordial, in order to refresh and excite again the system. Hence such almost by necessity fall into the habit of Intemperance, and alas! Bacchus may now-a-days be represented under Petticoats."

After his graduation Lettsom visited Paris and the great spas of Europe, then returned to London, the theater of his ambitions. In 1770 he

J. C. Lettsom. *Dissertation Inauguralis Medica, sententia Observationum ad Virum Theophrastum Bombastem, Leyden, 1769, pp. 1-8.* The English version quoted here is a manuscript translation signed "W.C.", which is the author's collection.

From the Department of Surgery, Division of Thoracic Surgery, Duke University School of Medicine and Hospital.

For Boswell's account of the occasion, see his *Life of Samuel Johnson*, LL.D. II, 82-83. London, 1791.

John Cockley Lettsom (standing center) is shown presenting to the Medical Society of London in 1788 the deeds of No. 3 Bolt Court, a house which was used by the Society for its meetings and library until 1850. Painted by Samuel Medley. In 1800, the picture shows also Dr. James Sims, wearing a Napoleonic hat, and Dr. Edward Jenner standing at Sims's left.

married the daughter of a wealthy tin-plate manufacturer became a licentiate of the Royal College of Physicians and began the practice of medicine. His success in practice was almost immediate as a result partly of the recommendation of his patron the famous Dr. John Fothergill partly of his own untiring efforts. He soon became one of the first physicians of London possessed of a town residence on Basinghall Street and ten miles away a country estate Grove Hill in Camberwell where his guests could choose among the entertainments offered by an extensive library, an excellent cellar, mineralogical and numismatic collections, a botanic garden with opulent greenhouses, a complete set of apparatus for experiments in natural history, in addition to a bowling green.

Lettsom's opinion of his own profession was a curious mixture of idealism and sentiment. He aspired to be far more than a healer of the sick; he thought the physician should be a consoler of the bereaved as well a guardian angel sent by Providence to support them in their misery; he should be a helper of the poor and a prime mover in all philanthropic endeavors; he should be not only a professional in medicine but also an amateur of all the sciences; he should be a gentleman and a scholar versed in history, literature—both ancient and modern—music and the other arts. In all these directions Lettsom sought to develop himself. Medicine and humanitarian pursuits demanded most of his time; the small remainder he devoted to scientific and literary studies or to pleasant recreations with his chosen friends.

Prince of Abyssinia, was perhaps his own picture, and it inculcates apathy to the world rather than happiness in it. Upon the whole, he seems not to have been a happy man; his religion was rigid rather than social, and his mind warped by system, rather than humanized by virtue and truth. But who is perfect? "

Cuming's answer leaves no question as to his conviction of Johnson's imperfections.

"I have repeatedly read over your Character of Dr. Johnson. I shall read it again and again: the features appear to be so accurately drawn with such a due proportion of light and shade: the praises given to his virtues and abilities so justly balanced by your candid acknowledgment of his failings and weaknesses, that I can better depend upon its being a just resemblance than on any other representation that books or conversation have ever given me of him. But yet, my friend—say, yet—though I ever admired the great extent of his literary abilities, and few perhaps possessed greater, I could never consider him as an *amiable* character. Conscious of the superior dimensions of his own abilities, he treated others who perhaps, were his inferiors, with a fastidious contempt. He always seemed to me sententious, oracular, and dogmatical in his assertions: stiff in opinion and hardly ever adopting that of others, however clear in opposition to his own, narrow and illiberal in his sentiments, respecting those who differed from him in religious or political tenets, and of those who had not the felicity to be born within the jurisdiction of England. His *Dictionary* will be confessed has singular merit, and exhibits a great extent of reading and judgment.

Cuming completes his letter by pointing out a few flaws in the dictionary. To this barrage of criticism Lettson replied with an account of the dinner at Dilly's.

In social company, when he unbended from critical austerity, Johnson afforded the finest dessert to a rational repast. I once dined with him, Wilkes, Boswell, and Lee the American,—what a group! It was ungrateful, said Lee, "for the Scotch, who, when emigrants, always found an asylum in America, to be the most violent opponents to American independence and to oppose their benefactors in the cabinet and in the field." The obligation replied Boswell, "was not so considerable, when it is understood that the Americans sent the Scotch emigrants to Cape Fear, and such like barren regions." I think, said Johnson, "they acted like philosophers. Why? Boswell inquired. Because, added Johnson, "if you turn a starved cow into clover, it will soon kill itself by the sudden transition and if the Scotch, famished in their own country, had been placed in the more fruitful parts of America, they would have burst by a bellyful, like the cattle in clover. Nobody enjoyed a laugh at the expense of the Scotch more than Boswell, at least when it came from Johnson and the latter appeared to do it in play: but his play was as rough as that of a bear, and you felt fearful of coming within the embraces of so fierce an animal."

In answer Cuming drew an invidious comparison between the gentle and courteous manner of Dr. John Campbell author of the *Survey of Brit* and that of Dr. Johnson then went on with anecdotes of his own acquaintance with the illus-

trious Bishop Warburton. He could not conclude without another blow at Johnson.

Notwithstanding all that you and others have said I must still think this said Dr. Johnson had a *ferine* malevolence in his disposition with a very narrow contracted heart, from the dislike he manifested for those who were not born in the same island. Can anything be more unworthy of a philosopher whose mind ought to be divested of all prejudice? "

At this point Lettson seems to have abandoned the futile defense: he has no more to say about Dr. Johnson. But Cuming raised the subject again in May 1786.

Dr. Johnson and his biographers have employed the press, and been the subject of most conversations ever since he died. That poor man's fate has been singular beyond precedent in the annals of literature. While he lived he was considered as an excellent classical scholar and the author of several works, some of approved merit, and others of an inferior character, but known as a man of a disposition sour and *introdable*, yet still he might have been handed down to posterity as a tolerable mixt character, in some points respectable, but no sooner was the poor man laid in his grave, than four or five of his most intimate friends took it into their heads, that he merited nothing less than deification, and to work they went with a determined resolution of elevating his character beyond that of any that has ever dignified or adorned human nature. But so peculiarly unfortunate have they been in their endeavors, that every effort they made to elevate has operated in a retrograde direction and these united efforts have dragged him down below mediocrity. His learning appears to be no ways superior to that of many others whose names have been less known. His political opinions were a jargon of nonsense, his religion a system of gloomy, weak, and slavish superstition. His temper arrogant, contemptuous, and unsocial his disposition vain conceited, sour and often malevolent. Upon the whole, he was a most unamiable being, and most of these failings the intemperate and injudicious zeal of his best friends has by a strange fatality brought to light. Boswell's and Poxon's works are wonderfully trifling and inconsistent. I am sorry to hear that Boswell is deaf to every remonstrance, and fear that this affair will end fatally for his intellects."

The biographers suffer even more severely in a letter which Cuming wrote on June 6 1787. He has been reading Sir John Hawkins life of Johnson and finds that the hero "loses ground in (his) estimation by every page that (he) peruse(s) and that Johnson's whole life seems to be a great aggregate of inconsistency want of judgment, strong prejudices, gloomy superstition supreme arrogance, and gross rudeness of manners." "And the biographers have brought all this to light

His character may be compared to Caesar's mangled robe, when displayed by Marc Antony to the Roman people, after the assassination—"Look! in this place ran Ptolema (Cassius) dagger! through this the well beloved Boswell (Brutus) stabbed! See! what a rent the envious Hawkins

(Cassia) made. And he is still doomed to further indignities by the publication of his Life threatened by Boswell.

It is not recorded that Lettison came to the defence of Boswell a fact which seems surprising when it is remembered that the biographer was a closer friend of his than ever Johnson was. They had probably met long before the Johnson-Wilkes dinner at one of the frequent parties that gathered at the Dilly house during the early seventies, and they must have met often during Boswell's many stays in London thereafter. Both men were present at a dinner given by Charles Dilly on October 23, 1787, when Boswell "was very low and injudiciously had recourse to too much wine to raise (his) spirits." They met again at Dilly's on May 9, 1790 and on July 20, when Boswell again "drank rather too liberally." John Nichols informs us that on occasions when Charles Dilly found it necessary to leave his guests earlier than he wished he deputed the pleasure of entertaining them to Boswell who sometimes, in that capacity, has tried the strength of the *oldest bin*.¹⁴ Whether or not Lettison was ever present on such an occasion he had ample opportunity to observe Boswell's convivial indulgences, for on June 18, 1791 he found it desirable to address to his Scottish friend a serious warning,

When I acknowledge that ever since I had the pleasure of thy acquaintance I have felt singular esteem for thee I only express a sentiment which every other person must feel if placed in the same situation. The generosity and candour the openness of thy heart combine to acquire and to secure the attachment of every liberal mind. This attachment I presume to claim. It is this that compels me to risk thy future friendship, in embracing the freedom which it inspires.

I have, my friend, had some occasion of leaving thee in the most interesting situations, when thy whole soul has been poured out in social enjoyment, I might have said ecstasy and in no point of less constant thy pipes more endearing, for those will love thee most who see most of thy heart. But in these scenes of pleasure which I have cordially enjoyed, sometimes sighs of solicitude have burst upon me lest by any unguarded excitement of such conviviality bodily constitution may be undermined, and that life thereby shortened which every man of refinement and virtuous sociality must wish long, very long preserved.

"I have observed, not merely a too frequent use of the glass, but that mixture of Bagnos which, as a professional man, I can add, tends to injure the best human fabric. I will add further that ample experience authorizes, that by whatever means the spirit is exhilarated beyond the chaste medium of nature the alternation of mental languor will result so that the depression is great in proportion to the degree of foreign excitement.

"Thy most exhortation me thus to recall sober reflection to chasten and to moderate the fascinating influence of social pleasures, either too frequently repeated or too long extended. I feel! the first place the emotions of friendship which I cannot repress, and in the next, the intrinsic solid sense of one I am proud to call my friend, these equally impel me to risk his censure whilst the latter encourages me to subscribe in self his sincerely

J. C. Lettison.

This letter Boswell apparently took in good part as he had taken similar advice from Johnson years before. He did not, of course, pay much heed to Lettison's warning in a letter to Lettison written six months later he partly explains his state of depression by admitting that he has not followed Lettison's friendly recommendations as to regimen. *Spero meliora*.¹⁵ Certainly Lettison took no measures to remove temptation from his friend's way. Boswell dined with him on November 6, 1793 and describes the evening thus

At Dr Lettison's as mercurius Company several of those whom I had seen at his house in Camberwell. We sat late and drank great deal of the St John Peter late Consul at Ostend, carried me in coach with his Lady to their lodgings in Leicester Square, and made me go up and take glass of Begerue and then was so kind as to proceed with me in the coach to my own door and see me safely to home I being good deal intoxicated.¹⁶

Boswell made one of the party at Grove Hill on several occasions his journal contains a pleasant record of one visit on August 21, 1790

At Dilly and I dined with Dr Lettison at his charming villa at Camberwell Grove A.M. — an old gentleman of Alverden who had lived long at St John's and had been 50 years without being in Britain, dined there as did Dr Sims, the Irish City Physician. We played 2 bowls both before and after dinner, the gentlemen of Camberwell, whose names I forget, has lag joined us. I refused the amusement much, and as conscious of being earned long the stream of life with no steady direction but without positive pain, for which I am so framed as to thank I may composed.¹⁷

The joys of the villa are more fully and fairly presented in an Horatian Ode to Charles Dilly,¹⁸ which Boswell composed in honor of Grove Hill and its master:

My cordial Friend, still prompt to lead
Your cause, when I have need on —
We both must bear on load of care —
At least talk and read on't

Yet are we gay in every day,
Not minding here the joke he
On Saturday at bowls & play
At Camberwell with COALLEY

John Nichols, Literary Anecdotes of the Eighteenth Century III, 92. London, 1800

Methinks you laugh to hear but half
The name of Dr LETTSOM
From him of good—talk, liquors food—
His guests will always get some

And guest has he in every degree
Of decent estimation
His liberal mind holds all mankind
As an extended Nation.

LETTSOM we view a Quaker true
'Tis clear he's so in one sense
His *Spirit* strong and ever young
Refutes perit PRIESTLEY'S nonsense

In Fossils he is deep we see
Nor knows Beasts, Fishes, Birds ill
With Plants not few some from Pellet
And wondrous *Mangel Wurzel*.

West India breed, warm heart, cool head,
The City's first Physician
By schemes *humane* Want, Sickness Pain,
To aid is his ambition.

From terrace high he feasts his eye
When practice grants a furlough
And, while it roves o'er Dulwich groves
Looks down—*even* upon THURLOW

Fortunately Lettsom's literary acquaintance included one who was a better poet than Boswell though his name is now nearly forgotten. John Scott of Amwell the Quaker poet who won Dr Johnson's difficult affections, was long Lettsom's friend and apparently his literary adviser as well.²² Scott's verses on Grove Hill take up with Boswell's closing note—the striking view 150 miles in circumference, which the site of Grove Hill afforded—then Scott turns to Lettsom himself

That business with fatiguing cares
For this delightful seat of thine
Such scanty store of moments spares
Sa friend, shall I for thee repine
Were it the commerce of the main,
Or culture of the teeming plain,
From blame or pity I should scarce refrain

But, oh, to alleviate human woes
To banish Sickness, banish Pain
To give the sleepless eye repose,
The nerveless arm its strength to gain
From Parents' eyes to dry the tear
The Wife's distressful thought to cheer
And end the Husband and the Lover's fear

Where Want sits pining faint and ill
To lend thy hand unpurchas'd aid,
And hear the exertions of thy skill
With many a grateful blessing paid—
'Tis luxury to the feeling heart,
Beyond what social hours impart
Or Nature's bounteous scenes, or curious works of Art

John Nichols, *Illustrations of the Literary History of the Eighteenth Century*, II, 661, 665 n. London, 1977, 735.
²²Pettigrew op. cit., II, 353.
²³John Scott, *Eulogy on Grove-Hill*, *Gentleman's Magazine*, LXX (August, 1795) 685.

The estate was celebrated in still another set of verses by the oriental scholar and historian, Thomas Maurice. A clergyman Maurice was a voluminous writer and one of the first to popularize the knowledge of the history and religions of the East. He wrote and published many poems, one of which Lord Byron scathingly described as the petrifications of a plodding brain. His rapturous poem on Grove Hill first describes Lettsom the physician, then Lettsom the botanist

Not on! man's frail race thy skill befriends,
Thy vegetable life thy skill extends

A tour of the Grove Hill botanic garden library and museum follows couched in the peculiarly maddening roundabout diction so popular with the worst eighteenth-century poets. The account of the library has some interest beyond its style

Science there has fix'd her favourite seat,
There cherish'd Genius finds a safe retreat
There honour'd and renown'd through every age
The mighty fathers of the classic page
Who wak'd, in Greece or Rome, the soul of song
Or roll'd the tide of eloquence along
Assembled in their deathless works appear
And seem to charm again the ravish'd ear
There too each great and venerated name
Enroll'd upon the page of modern fame
Sages, whose daring minds have nobly soar'd
And wide the spacious vault of Heav'n explor'd
Or darting downward, pierc'd the central gloom,
Where burning gems the boundless shade illumine
And mark'd great Nature in the secret mine
With chemic power the glowing ore refine
Patriots who proudly prodigal of blood
The rage of fercest tyrants have withstood
And statesmen, of unspotted honour prov'd,
By freedom cherish'd and by Britons lov'd
An awful throng in sculptur'd marblerown
And fire the soul to deeds of high renown

A few words on that library at Grove Hill will not be out of place and will serve to clarify the stilted phrases of Mr Maurice. It was a splendid collection ample in scope but particularly rich in medical and natural history. The many pieces of value included an unpublished letter of Hippocrates once the possession of Askew. Lettsom acquired it at a sale for ten shillings and sixpence, his agent Dr Sims having let the other bidders know by whom it was wanted.²⁴ Another notable curiosity was a seven volume work by Jacob Christine Schaffers in which the leaves of the volumes were formed of vegetable and other substances. The classics were represented in a collection of choice editions gathered by the printer

²⁴Thomas Maurice, "To John Coakley Lettsom, M.D. on the Improvements at his Villa of Grove-Hill," *Gentleman's Magazine*, LXX (August, 1795) 686.

²⁵Ibid., p. 686.

²⁶Pettigrew op. cit., I, 22123.

William Baker and purchased by Lettsom after Baker's death.

The library bookcases were divided into sixteen compartments, each topped by a bust of some personage appropriate to the subjects of the books beneath him.²⁷ Thus John Wesley presided over Tracts and Miscellanies Addison over Reviews Pott over Surgery and Chemistry Stukeley over Antiquities and Medals Hogarth over Prints and Maps Newton topped Arts and Sciences Locke Divinity and Law Bacon, Dictionaries and Classics Voltaire History and Biography Milton Poetry Raleigh, Voyages and Geography Boyle and Franklin Natural History Sydenham Medicine Fothergill Medicine and Botany Mead, Hortus Siccus and manuscripts.

Lettsom found it necessary to dispose of Grove Hill some years before his death and a part of his library which was too large for his town residence had also to be sold. It was auctioned off by Leigh and Sotheby during the week of March 26 1811. At his death in 1814 Lettsom still possessed a library of over 12,000 volumes which was sold by the same dealers two years later.²⁸

Lettsom's many other literary acquaintances can be mentioned only briefly. He was for decades the friend and physician of John Nichols, editor of the *Gentleman's Magazine* who described Lettsom as one who gladdened as well as lengthened life. Charles Dilly the bookseller was Lettsom's publisher and devoted friend throughout their mature lives, and at his hospitable table Lettsom met authors and scholars by the score. On his death Dilly left the physician a legacy of five hundred pounds. Lettsom's varied interests brought him the acquaintance of many philanthropists including John Howard and John Nield, of the botanist William Curtis, the naturalist Peter Collinson the mythologist Jacob Bryant. He corresponded widely with men of letters and science in other countries, with Rush, Franklin, and Waterhouse in America Zimmermann in Hanover and William Thornton in the West Indies—the last named was designer not only of the Capitol building at Washington but also of a universal alphabet calculated to solve all linguistic difficulties.

Lettsom held yet another place in the literary history of his time: he was always a generous and helpful patron to men of letters. As Pettigrew

writes "In him the sons of genius were sure to find a friend."²⁹ One of the writers who owed much to Lettsom's aid has been mentioned—William Curtis, the botanist. A result of Lettsom's awareness of the general neediness of the writing clan appears among his philanthropic essays, a paper entitled *Hints for Establishing a Society for Promoting Useful Literature*.³⁰ The proposed society would give rewards, pecuniary or honorary to deserving authors, would establish prizes, care for the widows and orphans of authors, and erect monuments to deceased genius. This "hint of Lettsom's is of particular interest for while itself ineffectual, it preceded by ten years the establishment of the Literary Fund.

Many institutions of learning, also owe a debt to Lettsom. From his American friends in particular he received many appeals on behalf of colleges and libraries. Dr. Rush wrote for Dickinson College in 1785

I know the pleasure you take in doing good. I know your zeal in promoting knowledge and hundreds testify to your partiality to the American States. Will you give me leave to solicit your friendship to our College in begging a few books from your friends for our library the improvements of their studies will be very acceptable in our illiterate western country. The number of the stalls in the streets of London, which are sold by night, could make as true rich.³¹

Waterhouse sponsored Harvard. James Boaden presented the needs of the college his father. To each Lettsom sent letters. In 1800 the managers of the Pennsylvania Hospital asked Lettsom's aid in purchase for their library, he not only supplied advice but also sent volumes from his library.³²

John Cookley Lettsom was convinced that the physician should be "a student and a scholar versed in history literature and the other arts, and shaped his life accordingly. Today in our struggle for the science, particularly as it applies to our fields, we as physicians too often neglect humanities, become narrow and limited in and fall to assume that leadership in our science which is our heritage. Certainly I am one of the greatest physicians of the eighteenth century as a cordial friend of literary men and generous patron of learned institutions also in a place, however small, in the annals of literature."

REVIEWS OF NEW BOOKS

THE book *A Textbook of Gynaecological Surgery*¹ is one that all gynecologists and surgeons should have in their library. It is both interesting and advantageous to have available a book which presents the English point of view and methods so excellently. The radical abdominal operation (Wertheim) for carcinoma of the cervix is thoroughly discussed. These authors have had a tremendous experience with this procedure. Their thinking on the subject is set forth clearly and all aspects are discussed. The current arguments concerning subtotal and total hysterectomies and vaginal versus abdominal hysterectomies are considered and their opinions are given.

Their conservative attitude toward removal of the ovaries is to be commended and their statements are well worth reading.

The chapters on Remote Results of Gynaecological Operations and Postoperative Complications are extremely interesting.

The dangers inherent in the performance of each surgical procedure are listed and discussed. This makes the book a handy reference.

The infusion and transfusion procedures differ quite widely from those carried out in America. On the basis of scientific knowledge our practices seem more fundamentally sound.

While the changes and additions in this edition are not numerous, the complete thoroughness of the book makes it valuable.

JOHN L. BARBER.

THE volume entitled *A History of the Heart and Circulation*² by Dr. Willis and Dr. Dry follows the general principle that history is composed of biographies. Thus throughout the work page after page introduces a new character usually with his portrait and an interesting statement of his contribution. In the first part of the book this biographical material is grouped into chronological epochs ending with the first quarter of the twentieth century. Then a very interesting series of special biographies is presented beginning with Hippocrates and ending with modern authorities such as Wenckebach, Mackenzie, Osler and Lewis.

There is in conclusion a section presented according to subjects such as arrhythmia, intracardiac circulation, surgery of the heart and blood vessels and so forth. Each chapter and division is accompanied by numerous references so that the volume, although

relatively small, is a starting point for any extensive and thorough review.

One may therefore urge that this book on the history of the heart be read for interest and education and that it may also be used as an important secondary source.

PAUL STARR.

THE second edition of *Intracranial Tumors*³ is a classical discussion of intracranial neoplasms written by Percival Bailey, a distinguished neuropathologist and neurosurgeon. It continues the tradition of the first edition published in 1933. Very few changes in content are readily apparent, perhaps indicating the stagnation of neurosurgical effort in the control or understanding of neoplastic growth during these 15 intervening years. The author states that the main thesis of the volume remains unchanged but errors have been corrected and recent advances in knowledge inserted. Sixteen plates depicting gross changes in the x-ray study of the skull, brain and cerebral vascular system during tumor development have been appended to the text. Only 33 of the 521 references represent material published since 1941.

The method of presentation of an admittedly difficult subject should be uniquely valuable to the student of neurology. The text may be described as a refined and readable version of lectures presented to students. It may be read with profit by any specialist in this field since it reveals one expression of neuropathological thought in a certain time period that may shortly be of historical interest alone.

The volume opens with a short discussion of the problem of tumors in general followed by two chapters devoted to the structure of the cranium and the elements of neurophysiology. Thirteen discrete cerebral tumors or tumors involving specific tissues such as connective tissue are then presented in separate chapters and are worthwhile reading for the student indeed. Each tumor or group of tumors is identified by brief historical notes. Several case reports are then detailed followed by a discussion of the gross and microscopic structure of the neoplasm. These pathologic features are illustrated by black and white drawings that do not fairly represent the author's vast knowledge of this phase of neurosurgery. Even if the microscopical drawings are intelligible to the student they must at least discourage any further pursuit of the subject.

The main substance of each chapter is found in the author's often lengthy but always lucid discussion of clinical neurological syndromes. These may be considered as superb lessons in neuroanatomy, neurophysiology and neurology pointed and

INTRACRANIAL TUMORS. By Percival Bailey. 2nd ed. Springfield: Charles C. Thomas, 1948.

¹ *A TEXTBOOK OF GYNAECOLOGICAL SURGERY.* By Victor Brenner, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.), Hon. F.R.C.S., Hon. F.R.C.O.G., M.R.C.P. (Lond.), and Sir Cornelia Berkeley, M.A., M.C., M.D. (Cantab.), F.R.C.P. (Lond.), F.R.C.S. (Frac.), M.M.S.A. (Hon.), F.R.C.O.G., 5th ed. New York: Paul B. Hoeber Inc., 1948.

² *A HISTORY OF THE HEART AND THE CIRCULATION.* By Frederick A. Willis, M.D., M.C., in Med., and Thomas J. Dry, M.A., M.B. Ch.B. M.S. in Med. Philadelphia & London: W. B. Saunders Co., 1948.

enlivened by the preceding case histories and the neuropathological data. These are "sharply defined syndromes characteristic of the various pathological types of tumors in different locations in the intracranial cavity" and nowhere in neurological literature have they been better presented.

The eighteenth chapter has to do with the matter of general diagnosis. It is marked by the sound but often disregarded, advice to the young physician to learn to use the ophthalmoscope as well as he does the stethoscope, by the author's aversion to the use of ventriculography and by failure to mention electroencephalography as a valuable adjunct in tumor diagnosis. The next chapter touches upon the various facets of differential diagnosis, a large subject in itself which the author presents in an effort to stimulate the student in his ancillary reading. More modern references, such as those of Ingraham in subdural hematomas in infants and those of Dandy in congenital cerebral aneurysm, for instance would aid in this worthwhile project.

The twentieth, and last chapter recounts the author's principles of treatment of intracranial tumors. Few neurosurgeons agree with one another in terms of neurosurgical technique, but there will be some who will dispute any use of intracapsular removal of acoustic neuromas or the advice to disregard the temporal intradural approach to pituitary tumors. Some neurosurgeons will use oxygen instead of air for ventriculography and will mention intratracheal ether as a good anesthetic agent. They will be happy to use the electrocautery in bleeding from brain tissue and gelatin sponge and hemostatic synthetic bone wax and tantalum clips and begin craniotomies with a transfusion rather than end them with such resuscitation methods.

In spite of these minor differences of opinion and the use of fourth decade techniques their results will be little different from those that are graphically and dispassionately revealed by the author. In this book the great contribution to brain surgery of neurology and tissue pathology are brilliantly disclosed by a master in these fields. Some part of the technical achievements of neurosurgery is at most suggested. The appalling impasse in which the surgery of cerebral gliomas now finds itself is all too obvious. The hope for the future does not lie in the direction of increasing our knowledge and acumen so that we can foretell before operation—the nature of the tumor to be attacked as well as its location." This hope has been in large part achieved. This volume can act as a standard springboard into uncharted waters whatever they may be but its philosophy of thought can produce nothing more. BARBARA WOODMILL

THE monograph *Osteosynthesis with a Long Intramedullary Metal Pin (Küntschers Method)* by Emile Jan Mödeys although not as elaborate as some other presentations, notably Böhrer's does add

*OSTEOSYNTHESIS WITH A LONG INTRAMEDULLARY METAL PIN (Küntschers Method). By Emile Jan Mödeys. Utrecht: Konink en Zoon N.V. 1948.

definitely to the literature on medullary nailing and is a work which can be read with profit by everyone interested in fractures. To some extent the method has been accepted in this country for the treatment of certain shaft fractures, and the opinion of a surgeon like Mödeys who reports after an experience with over 350 cases must be considered as definitely authoritative. Mödeys believes that "this method is a great advance in the field of fracture surgery" and even one with little or no experience with the medullary nail must agree with him after studying his essay.

The work discusses briefly at first the object of all fracture treatment and then gives more in detail the essentials of the method with separate headings for (a) reaction of the bone marrow, (b) possibility of fat embolism, (c) chance of infection, (d) general reaction to the presence of the metal pin, and (e) influence of the pin on callus formation. Apparently although there are definite temporary changes in the blood picture after introduction of a nail and some times until it is removed, no harmful effects have ever been seen and the possibility of fat embolism is no greater than in fractures treated by other methods. Mödeys goes into the subjects of the reaction of bone to metal as well as fracture and callus formation at some length. The chapter on the latter subject is well worth reading. He sums up by stating the use of the nail is ideal both in anatomical and functional respect and mentions that Böhrer reduced the hospital stay in certain types of femoral fractures from between 240 to 340 days to 45 days with the Küntschers pin. The second half of the monograph gives an excellent but short review of the literature and then discusses in detail the technique of the method as applied by the author. A special table is used and a roentgenologist is always present to guide the nail by means of the fluoroscope and the use of so-called "wringers," which are like large Thomas wrenches, to control the fragments. In open fractures this help is of course unnecessary as the guide wires are introduced at the site of the fracture. Mödeys states that the most important thing is reduction of the fracture and that by using his specially constructed table we succeeded in all cases. Then the operation itself is a minor procedure.

Details of 100 cases are given which add to the size of the volume but which add very little to the knowledge of the reader and can be skipped if desired. The bibliography is apparently very complete and can be used by anyone interested not only in the Küntschers method but in fracture healing in general.

The monograph should be available to all surgeons working in large well organized clinics where the method can be applied, but it probably will not be of any practical interest to the average doctor as yet.

WALLACE H. COLE.

IN *The Mechanism of Abdominal Pain* by V. J. Kinsella clinical investigations of abdominal pain

*THE MECHANISM OF ABDOMINAL PAIN. By V. J. Kinsella. M.B., Ch.B. (Syd.), F.R.C.S. (Eng), F.R.A.C.S. Sydney: Australasian Medical Publishing Co. Ltd. 1948.

are reported and an extensive bibliography is reviewed. Attention is called to the misconception concerning the absence of afferent fibers in the sympathetic nervous system. The author concludes that a belief in true visceral pain has an adequate anatomical basis and presents reasons for believing that direct visceral tenderness occurs. No sharp dividing line was found between sensitive and insensitive regions in the abdomen. A neurohumoral basis to replace the neuronal basis for abdominal pain is postulated. The effective stimulus for pain is raised tension within the tissues, due to inflammatory reaction or to powerful muscular contraction, or both. Tenderness in visceral disease is believed primarily and essentially to be that of the diseased visceral tissue; parietal tissues may be secondarily involved. Rigidity is believed probably due to a simple spinal reflex. The varieties of abdominal pain are recorded and the attempt is made to understand them upon the simple basis of direct visceral sensibility.

WALTER H. NADLER

THE little volume *Anatomía funcional del sistema nervioso Vegetativo* by Prieto and Uria approaches the neurovegetative system from a purely functional viewpoint. It is believed that to separate function from morphology is a mistake particularly inasmuch as no significantly new neuromorphologic contribution has been broached in recent times. The book is a compendium of a larger work in preparation on nervous functional anatomy. It presents the important features which have come to light recently and gives a résumé of modern thought on the matter.

Interpretation of the morphologic function of the vegetative nervous system has undergone numerous modifications; the fault of garbled nomenclature. The first chapter attempts to unravel this situation. Afterward such topics as the functional systematization of nuclei associated with peripheral nerves, functional localization of the hypothalamus, cranial parasympathetics, metasympathetics, innervation of the circulatory apparatus and other organs are considered in orderly chapters. The book concludes with an appreciation of vegetative sensibility and numerous unusually clear contrast illustrations make the volume a worthwhile acquisition particularly for the beginning student of neurology.

STEPHEN A. ZIEGLER

THE book *Chirurgie moderne de la hanche* appartient de la radiographie de profil by René Charny was not intended to be a comprehensive treatise on hip conditions. The author describes some of the more common arthropathies and their surgical treatment. Vitallium cup arthroplasty is not mentioned and hip lesions are not discussed. Great emphasis is placed on the lateral x ray view of the hip using the Judet

Mathieu technique which apparently is similar to that commonly used in this country under the name of Manfredi. The author points out the x ray findings in different positions of rotation and stresses the fact that the posterior articular margins of the hip in the lateral view are parallel. He discusses congenital dislocation of the hip as seen in the adult, and he distinguishes between subluxation and luxation. In the former osteoarthritis is the rule and invariably develops after the age of 35. On the contrary true luxation does not develop arthritic changes unless treatment was attempted in early childhood. The author supports his view with observations made in operative cases. In subluxation the lateral x ray view reveals that the posterior articular margins are not parallel and the femoral head is slightly displaced anteriorly. When this is recognized early an anterior buttress graft is indicated. The operation is technically difficult but it has the advantage of preventing the development of arthritic changes. When osteoarthritis has already supervened an arthroplasty is the treatment of choice. The author employs fascia lata to cover the femoral head. Vitallium cup arthroplasty is not mentioned.

The author continues with the description of other forms of osteoarthritis and atrophic arthritis pointing out that in these conditions the posterior articular margins of the hip are parallel in the lateral x ray view. He discusses the various operative procedures of neurectomy, drilling and pegging, shelf stabilization, osteotomy, Mathieu's resection, arthroplasty with their indication and their relative value. The latter procedure (which apparently is very similar if not identical with the Whitman operation) is preferred to hip fusion.

In cases of old luxation of the hip the author describes the accepted operative procedures (shelf stabilization, osteotomy) but in limited cases he prefers to do an open reduction, resecting an inverted V shaped segment of bone through the trochanteric region and transplanting the greater trochanter to the shaft of the femur. However since no end results and other statistical data are mentioned this procedure cannot be properly evaluated.

In coxa vara, the lateral view shows slight anterior displacement of the head. The author performs an anterior buttress graft and transplants the greater trochanter on the shaft. His results are excellent however again no statistical data are furnished.

Although the book is entitled *Modern Surgery of the Hip* the reader will not find in it such commonly accepted procedures as vitallium cup arthroplasty and Britain's arthrodesis. Apparently this was beyond the scope of the book. The text is well illustrated with 512 roentgenograms and tracings and makes interesting reading. C. L. JEANNOUD.

THE author of *Venous Thrombosis and Pulmonary Embolism* by Harold Neuhoof has been interested in the subject for many years. This monograph is

A FORTH THERMODYNAMICS AND PHENOMENA BY HAROLD NEUHOOF MD New York, Crane & Stratton, 1915.

LA ANATOMIA FUNCIONAL DEL SISTEMA NERVIOSO VEGETATIVO. By Ramón López Prieto and Francisco García Uria. Valladolid, España, 1917.
ANATOMIE MODERNE DE LA HANCHE. Appart de la Radiographie de Profil. By René Charny. Paris, Gasson Doin & Cie, 1916, 1915.

enlivened by the preceding case histories and the neuropathological data. These are sharply defined syndromes characteristic of the various pathological types of tumors in different locations in the intracranial cavity and nowhere in neurological literature have they been better presented.

The eighteenth chapter has to do with the matter of general diagnosis. It is marked by the sound, but often disregarded advice to the young physician to learn to use the ophthalmoscope as well as he does the stethoscope by the author's aversion to the use of ventriculography and by failure to mention electroencephalography as a valuable adjunct in tumor diagnosis. The next chapter touches upon the various facets of differential diagnosis a large subject in itself which the author presents in an effort to stimulate the student in his ancillary reading. based on a study of 88 fatal pulmonary emboli observed in an 11 year period at the Mount Sinai Hospital in New York between 1927 and 1938. All cases have been verified by autopsy and excellent diagrams are used to illustrate the site and extent of pulmonary emboli. There is a critical review of the literature and a new approach for the extraction of pulmonary emboli is described, which, while unsuccessful in this particular case, certainly merits further study and development. This method was first published in 1944 and no other report has followed this attempt.

Obviously the first part of the book was written later than the second. It contains a large number of histories with critical comments and illustrates the changing concepts in the author's mind toward more anticoagulant therapy. While in a controversial field as this lack of agreement is not unusual and invites further progress, one must point to certain discrepancies between the author's statements.

Thus for instance, while he is convinced that major pulmonary emboli, with the exception of a cardiac source, come overwhelmingly from the legs, he presents histories which show that lower abdominal pain (a pelvic thrombus) preceded the closure of the iliofemoral segment. He does not take much stock in the reflex effects of pulmonary emboli and yet describes two perfect examples of minor pulmonary emboli with a patent main pulmonary artery both of which were fatal with symptoms of a shock-like state. He does not mention the increased tendency to clotting

as an important factor in thromboembolic phenomena and yet describes cases in which propagating thrombosis occurred in the contralateral extremity under the customary dosage of heparin. One has the feeling that there is too much reference to part 1 in part 2 of the volume and that logically the first part, written later, should follow and not precede the second one.

With these minor exceptions, however the great merits of this monograph should be stressed. The author advocates an extensive search for flaccid thrombi free or adherent after sectioning the common femoral vein, he states that there is no dependable relationship between the location and extent of the pulmonary embolus and the clinical symptoms he veers more and more to anticoagulant therapy in calf muscle thromboses and does not believe in ligation of the superficial femoral vein.

The monograph is of interest to all general surgeons as it is a true account of the problems confronting them in their daily practice. Many questions, of course remain unsettled but it is through publications of this sort that an agreement can be reached as to the simple and safe measures to prevent and treat pulmonary embolism. While the presentation is repetitious, this is a provocative book which should be in every surgeon's library. Most refreshingly a detailed study of individual histories is presented in contrast to mass statistics, which often have the musty order of record libraries and seldom add diagnostic refinements.

the impression that the mother's food was even remotely a causative factor of malformations of the face and jaw. Recently Josef Warkany of the University of Cincinnati isolated and proved riboflavin to be the necessary ingredient in the prevention of malformations in mice which supports the contentions of those who blame the lack of certain vitamins. It has been shown that occasionally calcium retention is below normal. Syphilis sometimes plays a part. Cretinism, dwarfism, gigantism and infantilism have been accounted for on a glandular basis. Alcohol although long suspected as a factor has experimentally been found to have no effect upon the production of congenital deformities in the embryo of the laboratory animal. X-rays and contraceptives have been reported as etiological factors with associated substantiated case reports.

HEREDITY AND GENETIC EVIDENCE

Medical records are replete with histories and family trees showing the definite hereditary tendency of certain deformities. Hemophilia, allergy, albinism, many skin dystrophies, and other instances of hereditary influences are examples.

Hereditary characteristics are understood as being those characteristics, and physical or mental traits, which are present in parents or remote ancestors, and reappear among descendants in succeeding generations. This occurs by the fusion of gametes, or male (sperm) and female (ova) cells. The germ cells, or gametes, contain particular hereditary factors called genes which exert their action in determining future hereditary physical or mental characteristics.

To satisfy those advocates of environmental influence, it is admitted that any one individual personality or phenotype is a composite of internal, or genetic, and external, or environmental influences. An example of this is the measurement of school children in Oslo, Sweden, where it was found that in 1920 4,900 children were born and in 1933 2,100. Examination of these children and a comparison of these two groups showed that the average gain in weight in 1933 was 3.28 kilograms and in height, 3.89 centimeters. In comparing 1920 with 1933 it was shown that environment, due to smaller families, was undoubtedly the cause.

Geneticists recognize three groups of inherited defects: (1) the group in which the abnormality may occur in one or more sibs, but less often in their children or parents, the recessive; (2) the group in which the deformity is transmitted by direct descent from affected members of a family to some of their children who in turn transmit it, the dominant; and (3) the group in which the ab-

normality is transmitted by normal females and only affects males of the family the sex-linked.

The chance of inheriting an anomaly through the mating of an individual with a dominant anomaly and another individual either normal or heterozygous is 1 to 1. This chance in the mating of a recessive is 1 to 3. In the case of sex-linked inheritance the relationship is 1 to 1 to 1 to 1 the daughters carrying the anomaly and the sons being affected. It is worthy of note that as man is such a poor breeder and his family history is fragmentary or the size of his family is small the above ratio does not always hold.

Occasionally it may happen that a particular gene will undergo a change called mutation. Should this change occur in the germ tract, then the change will be transmitted to the offspring. These changes have been produced by Morgan and his coworkers and also by Bagg, as noted elsewhere. Hugo DeVries (reported by S. M. Titchett) in his experimental work with plants, has demonstrated that abnormal characteristics may appear spontaneously, are transmitted to offspring, and eventually disappear by crossbreeding; this is an example of the mutation theory of congenital abnormality in plant life. Abnormalities exist which can be due either to mutation or environmental modification. This duplication of the effect of a mutation by an environmental modification in an individual has been called "phenocopies" by Goldschmidt.

Morgan, in his Nobel Lecture in 1934, in which he implies a constant activity of genes, and that the character of the individual is determined by genes, asks why all the cells of the body are not exactly alike? What determines that some cells will be muscle, some nerve, and others reproductive cells? It is suggested not only that independent cell differentiation of individual cells takes place, but that an organizer exists between them all, causing cell interaction.

Morgan and his brilliant coworkers have proved that man inherits his characteristics in the same way as animals. The present relationship of genetics to medicine is still more intellectual than practical. In the United States, particularly, the genetic relationship of man is most complex because of the amalgamation of different migrating races. Moreover, medical advancement today keeps alive many defective types which in animal life would be automatically eliminated. Morgan believes further that genetics can assist in prognosing future deformities in a family following the presence of one deformity. He disparages the hope of purifying the race by proper breeding, but points out that should certain stigmata appear, genetics may

supply aid when the diagnosis as to disease or the suitability of marriage arises. Laurence H. Snyder, acting as a medical and consulting geneticist to Ohio State University has been one of the first to bring applied genetics close to clinical medicine.

New and extremely interesting work has been reported by Beadle and his associates. By means of *Neurospora*, an ascomycetous mold, studies have shown that the mutation of a single gene can block the synthesis of an essential cell constituent or prevent the utilization of a normal metabolite. In the human being the condition of alcaptonuria in which the ability to oxidize homogenticyclic acid is lost, differs from the normal by one single recessive gene. The conclusions reached by these investigators are as follows:

The synthesis of essential chemical constituents of living matter is under genetic control.

It seems probable that requirements of higher animals for dietary supplements of vitamins and amino acids are the result of gene mutations which have occurred in the evolution of the species.

It would seem that the primary action of the gene has to do with the synthesis of the enzymes which direct chemical activity in the cell.

In still another study, with *Neurospora*, it was possible to discover and maintain x-ray induced mutant strains characterized by their inability to carry on specific biochemical processes. Three mutant strains were established and in one the ability to synthesize B_6 had been wholly lost. In the second the ability to synthesize the thiazole half of the vitamin B_1 molecule was absent and in the third part, the aminobenzoic acid was not synthesized.

Since mutation may be produced experimentally, Kemp reviewed the conditions which one could reasonably assume might arise from mutation in the human being. It is believed that from 92 to 95 per cent of the genetic mutations are recessive although any given hereditary disease may be recessive, dominant, or intermediate according to the length of time that has passed since the disease-producing gene arose through mutation, the younger ones being recessive and the older ones tending to be more dominant.

Some of the conditions occurring as recessive mutations are hereditary dwarfism, hereditary deaf mutism, Friedreich's ataxia, amaurotic idiocy, hemophilia, and color blindness. Among the dominant mutations are hereditary hemolytic jaundice, Mongolian idiocy, Huntington's chorea, sickle cell anemia, and others.

On the basis of a dominant or recessive disease in the population and the fertility of the parents, it is possible to calculate the mutation rate for the

disease provided the frequency of the disease is constant from one generation to another.

Mutation as a cause of disease is dependent upon the frequency of the disease inheritance and the effective fertility of the patients affected.

GLANDULAR EVIDENCE

The inter relationship of the glands of internal secretion is too complex to dwell upon at this time. It is entirely possible that some one or group of hormones may influence the developmental rate and its fluctuations as pointed out by Stockard and Speeman. Mention may be made here of the few definite deformities directly ascribable to hormone influence. Evans gives the anterior pituitary lobe five separate hormones: (1) somatotrophic, (2) gonadotrophic, (3) thyrotrophic, (4) mammatrophic, and (5) interrenotrophic. Congenital deformities occurring under the first are growth hormones—as instanced by dwarfism and the cretinic dwarfisms due to a depressing effect on the anterior pituitary lobe by the thyroid. We are familiar with gigantism and acromegaly which may also be congenital.

Gonadotrophic hormones have been used successfully in treating cryptorchidism. Certainly one might well reason that this condition is caused by a diminution of this hormone during fetal life. Another instance of the possible effect of this hormone in experimental work is shown in the case of the Seabright chickens, the normal males looking like hens but following castration they become cocks in appearance. Moreover removal of the ovary causes the hen to take on the appearance of a cock.

True instances of the effect of the other anterior pituitary hormones and their positive relationship to congenital deformities is lacking. Hypospadias and hermaphroditism are both congenital deformities. They may well be due to sex hormones which cause a mutation of the sex genes. Goldschmidt believes this and has on record 2 cases of intersexual identical twins.

Both hypothyroidism and hyperthyroidism may be found in the infant and instances of their effects on development are readily brought to mind.

In the experimental evidence it was noted that frequently congenital deformities tended to predominate in the male, with an associated left-sided predominance, particularly striking in hare-lip. In this latter condition Warkany cites Fostyn's conclusion that hare-lip and cleft palate are inherited as a double recessive trait, one gene being autosomal and the other sex-linked. This should explain the predominance in the male. On

the contrary Bagg and Little noted a variance in that they discovered polydactylism in 61 females and 30 males. Sixty deformities were found on the right side, and 27 on the left. Bagg was unable to account for this distribution but quotes Huber who says that the left side of the body is less completely developed, and cites the overdevelopment and frequency of supernumerary fingers on the right side. In contrast, his mice showed club feet in 159 males and 131 females, the condition predominating on the left side (279, left, 205 right). Murphy found that the relationship between male and female was equal in his series however J S Davis and German state that the literature on syndactylism shows a predominance of males, and in their own particular series of 50, the males made up 68 per cent of the total. Davis also states that congenital clefts of the lip and palate show a 70 per cent predominance in the males.

Birkenfeld's 385 cases of harelip and cleft palate are classified in Table I.

Here, again the predominance of male over female and left-sided over right-sided involvement is striking.

Cockayne offers as a solution the presence of a dominating inhibiting gene in the x-chromosome which results in the excess of males. However following this hypothesis, analysis of several pedigrees of psoriasis, epidermolysis bullosa simplex, and angioneurotic edema shows exceptions that are incompatible with such a theory. He suggests that if one assumed that the presence of a sex linked recessive lethal gene caused the preponderance of males, then, at least, a working hypothesis would be afforded for such a preponderance.

EMBRYOLOGY

The problems of defective development, taken as a whole, have been placed in a state of transition by recent work of the school of experimental embryologists. This is essentially the result of the demonstration within the last two decades, of the existence of a complex series of causal embryological relationships, commonly referred to as "inductions." The ultimate scope and details of these physiological relationships are still largely a matter of future research and to this extent the problems of defective development have been placed in a state of transition, awaiting the further results of embryological research. However enough is known at present to indicate clearly that there can be no sound understanding of development if "inductions" are not brought into the picture.

Much of the basic research in causal embryology (the 'Entwicklungsmechanik' of the Germans) has centered around the development of the nervous system. In fact, the clarification of fundamental concepts subsequently applied to other organs has come to a great extent from this field of research largely in the hands of Spemann and his students.

The central fact established by the school of Spemann is the induction of the rudiment (Anlage) of the nervous system, the neural plate. An influence emanates into the future neural plate from the layers of cells just under it, the archenteric roof. Before this influence has been exerted, the rudiment of the nervous system, termed "presumptive neural plate material," has no capacity whatever to form nervous tissue. After the passage of the influence, the ectoderm can develop into parts of the brain or into spinal cord even if removed from the embryo and maintained *in vitro*. The early ectoderm, without the inductive stimulus of the archenteric roof is capable only of proliferation into a mass of cuboidal cells without specific histological characteristics. It obtains its usual differentiative abilities as a result of its contact with mesodermal or endodermal regions of the embryo.

Since the earlier experiments done by Spemann (1918 1924) it has been evident that the archenteric roof induces more than nervous system, and the range of its inductive capacities is now known to be very extensive, including most of the organs of the body. From the ectoderm the organizer has induced various portions of the brain as well as quite complete brains, auditory vesicles, olfactory pits, pigment cells, skin glands, and muscle. Also mesoderm and endoderm react to the stimuli from the archenteric roof although

TABLE I—HARELIP AND CLEFT PALATE

Degree of cleft formation	No.	Boys	Per cent	Girls
Harelip, left	24	37	60.5	17
Harelip, right	5	20	80.0	5
Harelip, bilateral	14	8	35.7	6
Total	43	65		28
Cleft of soft palate	22	9	40.9	13
Cleft of soft and hard palate	43	17	39.5	26
Total	65	26		39
Harelip left and cleft palate	15	73	82	11
Harelip right and cleft palate	48	28	85.7	6
Harelip bilateral and cleft palate	76	48	63	28
Total	139	149		90
Grand Total	285	218	76.5	167

not to the remarkable degree found in the ectoderm. This makes clear the reason which prompted Spemann to apply the term 'organizer' to the archenteric roof (and to the upper part of the blastoporal lip which becomes the archenteric roof in subsequent development)

Inductive influences very like those released from the organizer also emanate from dead tissues of many kinds, embryonic and adult. Various tissues from nearly all main animal phyla (e.g. man, rats, cattle, birds, reptiles, fish, worms, molluscs) can induce neural plates and other structures in the early ectoderm (Holtfreter). The tissues may be alive or killed by boiling, desiccating or centrifuging; they may be macerated and extracted with alcohol and lipid solvents. Dead pieces of tissue have induced brain with eyes, glandular masses, limbs, muscle and notochord from ectoderm. The mesoderm and entoderm also react but to a lesser degree than the ectoderm (Holtfreter).

The capacity to induce is by no means a property of any and all tissues and substances. Inert substances such as agar, starch, and paraffin have no effect. Plant tissues (such as banana and potato) have little or no inductive capacity (Holtfreter). Glycogen and cephalin, formerly suspected of inductive capacities, cannot induce when purified (Needham, Waddington, Nowinski, Lemberg, and Cohen). Egg albumin, pig fat, and animal charcoal are negative, while blood and fat of the mouse and certain muscles of vertebrates and invertebrates have only a slight inductive capacity (Holtfreter).

Needham, Waddington, and Needham showed that either extracts of amphibian eggs or of beef liver can induce neural structures. After saponification the inductive capacity of a given tissue such as liver remains mainly in the unsaponified fraction. Furthermore, the inductive substances are precipitated by digitonin which combines specifically with the sterols. This evidence points to members of the sterol group as the inductive agents (Needham, Waddington, Nowinski, Lemberg, and Cohen).

A group of German workers has claimed inductive properties for certain acids: thymo-nucleic acid and muscle adenylic acid (Fischer and Wehmeir). They have made similar claims for certain higher fatty acids such as oleic and linoleic acid.

Detailed accounts of this work have not yet appeared. Several synthetic, chemically pure substances (estrogenic hydrocarbons) have inductive capacities (Waddington and Needham).

Therefore, the conclusion that specific organs and tissues can be induced by the action of chem-

ical substances upon embryonic cells seems well grounded. Direct contact of the cells with the inductor is essential to the transmission of the effect. This fact alone has the greatest potential significance for the student of developmental defects. Any aberration of development which tends to prevent close contact with the inductors would prevent or modify the development of specific organs.

Research upon causal factors in the development of the separate organs and tissues of the body in numerous instances is revealing a setup like that for the neural plate. It will be sufficient to concentrate upon a few specific, well worked out instances to bring into relief those principles which seem of greatest importance to the student of the origin of developmental defects.

Induction factors are particularly clear in the development of the components of the eye. The optic cup, arising from the anterior portion of the neural plate, is induced by the underlying portion of the archenteric roof (Mangold, Spemann, Holtfreter) which is thus the inductor of the optic cup. Transplantation of this inductor under the belly epidermis of another germy gastrula results in the induction of a piece of brain with eyes in the foreign location. Removal of the inductor at the proper stage results in absence of the optic cup. The inductive process is evidently a step-by-step affair since a series of abnormalities including cyclopia and various degrees of fusion of the two optic cups can be produced experimentally by varying the stage at which the eye inductor is removed (Adelmann, 2).

Stockard and others, up to Wright and Wagner, have adopted the assumption that eye defects represent the environmental or hereditary influences exerted upon the eye material itself. Reinvestigation of the effects of noxious environmental conditions such as lithium chloride upon the appearance of eye defects have placed this former conclusion in doubt (Lehmann, Tondury). The development of the eye inductor is clearly abnormal in every case of cyclopia. An examination of the numerous extranuclear defects which accompany cyclopia and otocephalia points strongly to the conclusion that the primary injury occurs in the eye inductor (Adelmann). On the theory of direct optical injury it becomes difficult or impossible to explain the abnormalities of the jaws, nostrils and head muscles. The possibility of direct optical injury has not, however, been ruled out completely.

The optic cup in turn is the inductor of the optic lens (Spemann, 22) and here too the inductive action is evidently a step-by-step process.

The initial stages of the process result in the development of the lens vesicle, but this is not endowed as yet with the capacity to differentiate the lens fibers. Further influence of the inductor is essential to the continued development of the lens. Parts of the brain near the ear apparently can also induce lens (Huxley and DeBeer). The dependence of the lens on the inductive stimulus of the optic cup varies, however, in various forms that have been studied (Spemann 1918). This does not mean that the lens can arise without the inductor for the ectoderm never forms a lens if it is separated at a sufficiently early stage from the rest of the egg (Holtfreter).

The lens in its turn, is the inductor of the conjunctiva. A conjunctiva fails to form after the removal of the eye, the ectoderm remains opaque and pigmented. On the other hand, transplantation of the optic cup, the lens, a piece of retina, or even a macerated optic cup to the belly region results in the formation of conjunctiva out of belly epidermis (Huxley and DeBeer). This condition of multiple inductors for a given structure is apparently a widespread phenomenon. Just what the interrelationships of the several inductors are during normal development is still problematical. Possibly one of them is the predominant agent, backed up by the others if the predominant agent should fail to exert its effect.

Viewing the development of the eye as a whole, we see a chain of inductive reactions: Archenteric roof (organizer) — optic cup — lens — conjunctiva.

The chain of reactions involved in the case of ear development is especially worthy of notice since it illustrates another aspect of induction: the mutual effects. Ear vesicles are induced from early ectoderm by implantation of the organizer of the hindbrain portion of the neural plate or the anterior part of the neural crest (Holtfreter). The ear-forming ectoderm never forms anything resembling an inner ear if it is isolated completely from the ear inductors. The ear vesicle serves in turn as the inductor of the cartilaginous capsule of the ear. It was found early (Lewis) that abnormal chondrocrania, lacking in auditory capsules, follows extirpation of the vesicle. The effect exerted is probably a chemical one since other portions of the body such as olfactory pits and pieces of brain, or inert materials such as paraffin or celloidin, placed into the ear region do not stimulate the formation of an otic capsule (Kaan).

The capsule then exerts an effect back upon the ear vesicle, for in the absence of the constraining capsule the epithelium forms irregular cystic

vesicles rather than the typical membranous labyrinth (Kaan). This is apparently a purely mechanical effect. The membranous labyrinth is still, however, apparently not freed from its dependence upon inductive stimuli from the hindbrain. Boonewie in a study of the waltzing mice, known as "Shakershort" mice found their behavior was due to degeneration of the labyrinth. Up to the eleventh day development is to all appearances normal. Then the hindbrain fails to send out nerves into the labyrinth, which subsequently degenerates. Apparently the nerve failure is the causal factor of labyrinth degeneration. Possibly the defective behavior of the hindbrain itself goes back to faulty induction by the archenteric roof but this has not been shown.

Quantitative aspects of inductive action have received comparatively little attention. However, there is promise of results of vital importance to the understanding of defective development. Mangold showed that the size of the neural plate is roughly proportional to the amount of inducing material. Microcephalia may be produced experimentally by a reduction in the amount of organizer (Tondury). The size of the mouth depends upon the amount of mouth inductor that contracts the ectoderm (Holtfreter 9). The amount of olfactory epithelium apparently depends upon the spatial extent of the stimulus emanating from the telencephalon (Holtfreter 9). An abnormally small lens results when the amount of optic cup is reduced (Spemann).

Many inductors are apparently equipotential systems in that portion of the inductor may induce a complete structure. Thus twins with separate or partly fused central nervous systems and notochords may be obtained by inserting a piece of tissue into the center of the organizer area (Bautzmann). Supernumerary proctodea may be produced by splitting the proctodeum at any early stage of development (Schechtman). The production of conjoined twins in amphibia by involution of eggs probably involves a mechanical splitting of the organizer by shifting of the heavy yolk material under the influence of gravity (Penners and Schleip). Many of the variations of twinning recorded for man and the higher mammals may be duplicated experimentally in amphibia by proper surgical manipulation of the organizer. It is possible that some cases of supernumerary organs result from excessive amounts of inductor rather than from splitting. Holtfreter (9) found as many as five olfactory pits induced in close proximity by a single implanted piece of organizer. Possibly the inductive stimulus here was a very diffuse one.

By far the greatest part of the results of causal embryology have been and are being obtained from amphibia. The results thus far seem applicable to every vertebrate adequately investigated. In the chick, secondary nervous systems are induced from ectoderm by implantation of parts of the primitive streak (Waddington). Conditions essentially similar to those in the amphibia occur in teleost fishes (Oppenheimer). Waddington showed that in the primitive streak stage of the rabbit, the ectoderm of the embryonic shield develops into neural tissue if placed in contact with a piece of organizer from the chick. He (Waddington) later showed that the primitive streak of the rabbit can induce neural tissue in chick ectoderm.

It may be concluded that mammalian development like that of other vertebrates, is controlled by organization centers and that the primary organization center for the embryonic axis is the primitive streak (p. 288).

Some defects with a hereditary basis, such as the otocephalia of guinea pigs reported by Wright, the cases of human cyclops reported by Klopstock, and the microcephalia which is sometimes present in feeble-minded human beings, can be produced experimentally by injury to inductors. How the genes act in the production of hereditary defects is not known; indeed it will not be known until more information is amassed on the basic problem of the relations of the genes to normal developmental processes. The possibility must be kept constantly in mind that genic effects like those of noxious environmental conditions, may be exerted not upon a given organ but upon one of the links in the induction chain leading to the development of the specific organ.

It is unnecessary to go on citing the inductors and induction chains which have been discovered. Each specific organ must be considered individually and, even then, only very tentative conclusions can be drawn since in practically all cases knowledge is still fragmentary. It is however clear from present day results that the variations in the properties of inductors must be included in concepts concerning the origin of developmental defects.

STATISTICAL STUDY

We are indebted to Douglas P. Murphy for his exhaustive study of many phases of the problem of congenital malformations. In the files of the Bureau of Vital Statistics, Department of Health of the State of Pennsylvania, 130,132 death certificates for stillborn and liveborn individuals who died in Philadelphia during the 5 years between January 1, 1929 and December 31, 1933 were examined. In 1,476 of these cases, the existence

of a congenital defect was noted. This defect was either on the body surface or, if internal, had been discovered either by operation or autopsy and confirmed in 890 of the original 1,476 cases. For the various studies an attempt was made to interview the mother of each of these 890 individuals. The visits were made by fourth year medical students. Controls were located through the licenses on file in the Marriage License Bureau of the City of Philadelphia for the years 1929 through 1933. Ninety per cent of the defectives studied were either stillborn or died within a year of birth.

Race. Deaths due to or associated with the presence of congenital malformations in white persons in Philadelphia for the 5 year period studied occurred at the rate of 9.6 per 1,000 of all deaths of white people. For the negro population the rate was 5.2 per 1,000, making the malformation death rate in whites nearly twice that of the negroes. Murphy states that the figures from the United States Bureau of Census also show that congenital malformations occur much less frequently in negroes. The frequency of such defects in the yellow race lies between these two extremes. If syphilis is about twice as common in negroes then Murphy's investigations suggest that syphilis plays little or no role in the production of congenital defects.

Sex. Males and females were affected equally by congenital deformities.

Birth Order. The birth order was studied in each normal and each malformed child. This investigation was prompted by various conflicting reports. Still had concluded from a study of malformed children that congenital heart disease and congenital pyloric stenosis appeared more often in the first born than in the later born. Macklin reviewed 1,000 cases in the literature and concluded that there apparently was no more likelihood of defects in the first than in the later born. Studies made on the birth order of mongols by Pearson and Ordahl all agree that mongols occur more often among the later births than could be expected by chance. Murphy found that the defects occurred in the first 4 children in families with practically equal frequency. However from the fifth child on, the incidence of malformations rose rapidly. Thus the seventh child appeared to be malformed twice as frequently as did any of the first four children.

Maternal age. From a study of 607 cases it was found that malformed children were born more often to older mothers than to younger ones. Between the maternal ages from 15 to 30 years the defective children appeared with about equal fre-

quency but the frequency of malformed children became three times that which was observed during the period before 30 years of age after the mother became 40 years of age.

Month of conception. Contrary to the reports published by Petersen and Paddock, Murphy found that his study offered no evidence for the belief that the conception of defectives is related in any manner to weather condition. In Philadelphia the greatest frequency occurred in the summer months which is exactly contrary to Petersen's findings.

Reproduction before and after birth of malformed child. Miscarriages and abortions were observed to appear in close relation to the pregnancy which ended in the birth of the malformed child. Premature births and stillbirths also were in evidence. Moreover these disturbances occurred most often in the pregnancy just preceding that which ended in the birth of the defective and next most frequently in the one just following. It was concluded that if a defective child is to be born, it is more likely to follow an abortion, a miscarriage, a stillbirth, or a premature birth.

Type of defect to appear in a second malformed child. In a series of 40 families having two or more congenitally malformed children the defect observed in the first child occurred in one of the subsequent defective children in 47 per cent of these cases.

Duplications of malformations among distant relatives. In 39 cases a distant relative of the malformed child showed a congenital malformation. This defect was identical in 41 per cent of the instances.

Frequency of defects among brothers and sisters. This study was done in an attempt to throw some light on the question of the possibility of parents of a congenitally malformed child having more malformed children. The investigation covered a consecutive series of 375 families each known to have had a congenitally malformed child and also one or more subsequent members. Thirty-four or approximately 12.4 per cent, of the families produced one or more additional congenitally malformed members.

From this study it is concluded that the offspring presenting congenital malformations which are serious enough to warrant being recorded on death certificates are approximately 24 times as likely to occur in families possessing a congenitally malformed child as in the population at large.

Relative sterility before birth of malformed child. The lengths of intervals between 2146 pregnancies of mothers of malformed children were determined. A long period of relative sterility occurred four

times more often immediately preceding the conception of the malformed child than at the birth of a normal child.

Duplication of rare defects. Maldevelopment occurs more frequently in the left dome of the diaphragm than in the right dome. One mother gave birth in successive pregnancies to 2 children, both with an absence of the right dome.

Duplication of defects through two wives. One father had a child with a cleft lip and a cleft palate on the right side by each of 2 wives.

Frequency of reproduction. Two hundred and eight families each had 2 or more children born before the birth of the congenitally malformed child. There was no significant difference from a series of control families. Thus rapidly repeated childbearing was not found to be a predisposing cause in the production of congenital malformations.

Diet. The diets of 545 mothers were investigated. No significant deficiencies were found.

Coincidence of malformation with placenta previa. Placenta previa occurred once in 741 malformation pregnancies. The frequency in the general population as quoted from Williams is about 1 in 1,000 cases.

Parental age difference. This study was based on an investigation of 600 parents with defective children and 600 controls. It was concluded that there is essentially no difference in the distribution of parental age differences.

Intervals between pregnancies. Based on a study of 531 families, it was concluded that mothers of congenitally malformed children tend to experience a more or less prolonged period of reproductive inefficiency at the time that the congenitally malformed children are born.

An exceedingly large number of malformed offspring were born after nonpregnant intervals of more than 4 years duration.

RUBELLA, CONGENITAL DEFECTS FOLLOWING MATERNAL INFECTION

The most interesting and apparently definite association between virus disease and congenital defects was first brought out by H. McAlister Gregg at the annual meeting of the Ophthalmological Society of Australia in October 1941. Rubella was widely prevalent in Australia during the years from 1937 to 1942 and there was an epidemic in New South Wales in 1940. During 1941 cases of an unusual type of congenital cataract were being seen in Sidney. Gregg states that these cases all showed a remarkable similarity of the opacities in the lens and frequently presented an accompanying affection of the heart. The cata-

facts were of the dense nuclear type and according to Gregg there was no similarity in their appearance to any of the morphological types of congenital and developmental opacities reported previously. It was postulated, on the basis of the widespread geographical incidence, that some common factor was at work. The German measles epidemic of 1940 seemed to be a likely suspect.

Gregg reported a series of 78 cases of congenital cataract which occurred in babies between December 1939 and January 1941. In 44 of these babies a congenital lesion of the heart was also noted. The mothers had suffered from rubella during the early stages of pregnancy.

In a later report Gregg, in discussing congenital defects in general, wonders if disease other than rubella may not have a harmful effect on the developing embryo. This author regards rubella and its sequelae as but one chapter in the full story. Previous to 1940 cases of congenital defects following maternal rubella during pregnancy had occurred but the relationship had not been recognized.

On the basis of Gregg's preliminary observations, a committee was appointed by the Director General of Public Health of New South Wales to investigate the occurrence of congenital defects in children following maternal rubella during pregnancy. This report was based on a study of 180 cases of children suffering from congenital defects. The committee was satisfied that the maternal infection was rubella with 'possibly an increase in the virulence of the organism.' The defects noted were deaf mutism, eye and heart disease, and possibly mental defectiveness. A large number of the affected children were below normal average birth weight and showed a degree of microcephaly. The majority were below average in physical development. A retardation of eruption of the teeth was noted but all had their normal complement at 3½ years of age. Dental defects in some of these cases had been described by Evans.

The committee further concluded that if the maternal infection occurs after the second month of pregnancy there is less likelihood of eye defects. No relationship was established between the severity of the maternal infection and the nature of the defect in the child. There was no evidence collected to show that there was any harmful effect on the mother or on the subsequent pregnancies. The children affected were regarded as mentally retarded rather than mentally defective. The deafness was not absolute and there was apparent improvement in hearing about the latter part of the fourth year.

Sivan *et al.*, in 1943 confirmed Gregg's findings. Their conclusions were based on a study of 49 mothers who had suffered with rubella during pregnancy 4 who had no knowledge of any disease during pregnancy none who had suffered from morbilli and 2 who had suffered from mumps. All these cases occurred in the years 1939 to 1943. Among the cases of rubella during pregnancy 31 of the infants born subsequently had congenital defects. The abnormalities noted were cataract deaf mutism heart disease microcephaly and mental retardation. With 2 exceptions, all of the 31 mothers had contracted rubella within the first 3 months of pregnancy. If the rubella occurred during the first 2 months of pregnancy every infant showed some defect. After the third month of pregnancy rubella caused practically no harm to the fetus.

No congenital defects were found in babies born subsequent to the occurrence of morbilli in pregnancy. Swan *et al.* record one case of congenital corneal opacity following mumps in pregnancy.

Numerous reports have followed from England and the United States. Prendergast in the fall of 1944 made a survey in California on the incidence of congenital malformations among children whose mothers had rubella during the first 3 months of pregnancy. The reports were made by 37 ophthalmologists 24 pediatricians, and 32 obstetricians. Although it was believed that there was probably some duplication of cases 80 cases of congenital cataract, 10 cases of other ocular defects 32 cases of cardiac defects, and 10 cases of other congenital anomalies were reported.

Because of the greater number of cases reported from the Western United States, Prendergast raises the question as to whether such congenital defects are more prevalent in the Western United States or whether the condition has spread from Australia to the Pacific Coast. The question of virulence of the virus is also raised. The malnourished appearance of the infant at birth with the inevitable feeding problems and lack of normal development were also noted in these cases.

Fox and Borten have reported 5 cases of maternal rubella in the first 2 months of pregnancy with only 1 abnormal child (stillborn and hydrocephalic). However the preponderance of evidence would suggest that all of the mothers who contract rubella during the first 2 months of pregnancy and half of the mothers who contract it during the third month of pregnancy will give birth to infants with congenital defects.

Rubella has been rather definitely established as a virus infection (Hiro and Habel). Mann as reported by Gregg was of the firm opinion that it

had been proved beyond question that there is a causative relationship between a virus infection early in pregnancy and the appearance of certain congenital defects in the child. Only those cells which are in active division would be affected. Gregg states that the lens of the eye and the inter ventricular septum develop between the fourth and eighth fetal weeks of life.

EXPERIMENTAL EVIDENCE

Sokolow after examining 1,302 healthy and 1,835 sick children, concludes that sick children possess a greater number of complications of extreme morphological variations than healthy children. The basis of these inferences is that these children are constitutionally inferior. Of 172 healthy infants, 10 or 5.8 per cent had deformities. Of a second group of 158 sick infants, 39 or 24.6 per cent had deformities.

The report of Harris on Stockard's attempts to explain human abnormalities on the basis of his experiments with heavily alcoholized guinea pigs, and on the efforts of Durham who repeated the experiments but was unable to verify them or find any change in the offspring, suggest that the problems of artificial production of abnormalities should not be loosely applied to the human being. The largest number of pathological ova and embryos are found in the first 8 weeks, after which time the number decreases. Pathological ova that survive the eighth week tend to live and are born as monsters. It has been suggested that threatened abortions early in pregnancy should not be treated by rest and quiet because it is quite possible that the uterus is attempting to rid itself of a pathological ovum. Studies of pathological ova by Harris indicate to him that ectopic implantation is a greater factor than uterine disease and that both are more important factors than maternal or paternal germ plasma. Of ectopic pregnancies, as many as 95 per cent produce monsters. This anatomical fact, Harris feels, is a strong argument against the germinal theories in the production of monsters. The primary theory in the majority of cases is that the environment of the ovum, through faulty implantation of the chorion, malnutrition of the ovum, or actual uterine disease, prevents normal development. The argument for environment as against the germ plasma is afforded by experimental teratology. By experiments almost all main types of monsters occurring in man can be produced artificially in the laboratory by interfering with the nutrition or environment of the normal ovum after fertilization. Examples of this are afforded by Spemann who produced double monsters in a frog by tying

a fine thread around the egg. Loeb showed that the heart's development could be checked by the addition of certain percentages of calcium.

Morgan produced spina bifida in frogs by raising the concentration of common salt each day. Stockard, Spemann, and others have produced cyclopia in fish and frogs by the action of magnesium salts. Warkany has caused harelip, cleft palate, fusion of the chest bones, and malformation of the claws in rats by withholding riboflavin from the diet. In all of these experiments, irrespective of method elected—chemical, thermal, or electrical—the malformation has been caused by interference with normal growth.

Harris states that from a study of human embryological material it has been estimated that only 1 infant in 20 showing deformity of the extremities has any family history. Against the view that many deformities of the limbs are due to mutation in the germ plasma are the proved examples wherein such deformities die out in later generations. This tendency of deformities to die out within three or five generations, Harris contends, is today awaiting explanation in terms of mutation of the germ plasma.

Mall held that a defective maternal environment—usually in the nature of faulty implantation—is the source of morbidity in mammalian embryos. Moreover he thought that pathological human ova and those obtained in the laboratory on experimental animals were identical.

Stockard has attacked the problem by experiments with the marine minnow *Fundulus*. Apart from those anomalies which are admittedly hereditary and transmitted through the germ plasma, this investigator believes that he has reduced the primary cause of all abnormal developments, including twinning, to a single factor mainly developmental inhibition or arrest. In this conclusion he is in agreement with Newman's conception of monster production through the lowering of the developmental rate. The exact type of deformity that results depends solely on the precise moment when the interruption occurs. All anomalies may be induced by the same kind of experimental treatment, while any particular type may be produced by a wide variety of different treatments. Stockard's method was a lowering of the temperature or diminution of the oxygen supply which means a reduced metabolism, and specifically the retarding of oxidation, and this is identified as the causal agent behind arrests and all anomalous development. The success of the procedure rests on the observation that the developmental rates of the embryo as a whole and of its component parts are not uniform on the contrary periods of rapid

progress alternate with moments of relative quiescence. Artificially slowing development during a time of normal retardation has little or no effect, whereas the same treatment during a phase of activity is productive of abnormalities. As to individual malformations, there are critical moments in the development of every organ or part which are characterized by rapid cell multiplication. At such times this particular proliferating region is dominant and may even exert a depressing influence over the growth of other parts. If this favorable moment for differentiation is not taken advantage of the transient supremacy of the organ is lost and in turn it submits to depression by other parts assuming their dominant periods. The result is a reduced or imperfectly formed region which has missed its opportunity to express itself completely or perfectly in competition with other parts. The conclusion is that each organ not only originates from a definite embryonic area or primordium and from no other, but also that it arises at a very definite moment which must be utilized at that time and no other. Corner studied 535 pregnant uteri from the domestic sow and noted that the ova and embryos of fertile parents suffer pathological change in the midst of a normal environment. This was discovered by histological examination of the uteri. Moreover the defects of ova and embryo occurred at all stages of pregnancy and were not all dependent upon specific maternal causes such as faulty implantation. Thus, Corner concludes that embryonic morbidity arises in part from internal defects of the germ cells and embryos.

The work of Bagg and Bagg and Little is of importance in this study. Mice were subjected to roentgen rays and later bred. Among the congenital deformities appearing were those of some of the extremities. These mice were then interbred for nineteen generations with a suitable control group of animals. Many fetuses were examined in utero and if they showed deformity they were identified by the amputation of their tails and then allowed to go to term. Of 5,000 studied in the inbred series, 413 had foot defects, 300 clubfeet with syndactylism, 9 syndactylism alone, 27 hypodactylism, 16 congenital amputations, and 93 polydactylism. Bagg concludes:

The earliest foot defect is associated with the formation of a blister like bleb which raises the epithelium of the foot usually in a localized area. This condition is usually found during the twelfth to the fifteenth day of prenatal life, and is followed by the escape of blood into the bleb and the formation of a localized blood clot. These blood clots may persist until birth.

The extent of the pathological process and its anatomical location determine whether the later developing foot is to show either congenital amputation, clubbing, hypodactylism, polydactylism or syndactylism.

Polydactylism in my experimental strain of animals may also be an expression of localized arrest in embryonic development.

Abnormalities of the limbs are definitely inherited. They are recessive to the normal in inheritance. When considered as one of the manifestations of a general tendency to abnormal structure they approach the Mendelian expectation in behavior.

Bagg further explains hyperplasia by referring to Stockard's work on arrested development as quoted and believes that such an arrested development occurred in the 12 instances of polydactylism found after the 5 year examination of 528 animals. Of these 12 8 showed polydactylism with a slight moderate clubbing, 1 polydactylism and syndactylism in the same foot and 3 polydactylism and hypodactylism. Remnants of hemorrhages were found in 8 of these animals.

Bonnevie continued the observations of Bagg and Little. She found that the clear blebs contained cerebrospinal fluid that escaped into the subcutis through the foramen arterius an embryonic structure on the roof of the fourth ventricle. This structure is normally a safety valve guarding against increased cerebrospinal pressure in the embryos and vertebrates. It exists prior to formation of the foramen of Magendie. In embryos developing blebs, the amount of escaping fluid or the rate of flow is increased. It is observed that the fluid has a tendency to collect in the concavities of the embryonic surface and ends in the limb buds and that the blebs are apt to be damaging to the further development of the embryo only if there was extravasation of blood into them. The preponderance of lesions on the left side is considered to be due to the intrauterine position or right-sided twist assumed by the mouse embryo.

Engel lists a series of congenital syndromes in which the formation of spinal fluid blebs in the subcutis of the human embryo may constitute an etiological mechanism. He finds the present differentiation artificial and notes that all of these syndromes have in common a combination of anomaly of the skull deformity of the extremities, and a tendency toward familial occurrence. Among these conditions are Mongolian idiocy, cranio-carpotarsodystrophy, and oxycephaly. These are under the blood disorders and are regarded as comparable with the experimental conditions produced in the Bagg and Little mouse strain.

Kanavel does not accept this interpretation of hyperplasia or its application to reduplication, and speculates upon whether it might be due to metaplasia of the cells in the involved part secondary to an injury of the vascular or nervous system in the germ plasma. Further he asks why the known predilection of these deformities for certain parts of the arm and forearm still remains unexplained.

Browne puts forth the interesting theory that mechanical pressure may play a part in causing certain bony deformities. He substantiates his premise with photographs showing talipes equinovarus, double talipes, malposition of the toes, postural torticollis, and fractures of the tibia. His excellent pictures show pressure dimples over points of contact of the feet, hands, elbows and heels in such a way as to make this rather extreme hypothesis seem quite plausible.

Because of the increased hydraulic pressure, Browne reasons the waves of blood sent into the fetal circulation supply the muscles of the viscera closest to the impulse and that the areas furthest away suffer from not only reduced arterial blood supply but also from venous stasis. Hence degeneration of muscle and stiffening of the joints would occur.

Certain other deformities of the extremities and maldevelopments have been traced to incomplete development of striated muscle and its replacement by either fatty degeneration or connective tissue. The muscles have also been lacking in striation. It would seem, however, that this lack of muscle development is just one phase or process of the problem.

Streeter reduces the problem to the egg itself and offers six specific examples of the character of egg material:

1. Variation in egg quality. This variation is shown in the work of Corner.

2. Variation in vitality of the body cells. Various cells such as fat and intestinal epithelium can live 18 hours under the same influences as kidney epithelium which persists after 120 hours. Carrel's experiment with the longevity of heart muscle is another example.

3. Excessive growth response such as by gigantism when confined to a special part of the body.

4. Deficient growth response, instanced by interuterine amputation. Further reference is made to the controversial question of umbilical cord and amniotic band influence. Because this particular example is thought to be an important factor in deformities, Streeter's opinion is worth recording here. He states that this condition

occurs in living infants otherwise normal, but that to be tenable the cord should be caught in the act of constriction and the tissue proximal to the constriction must be living, while that which is distal must show signs of disturbed circulation and necrosis. Moreover the cord must maintain its own circulation although tight enough to constrict the limb.

The amniotic bands and adhesion theory can be no better supported. The embryology of the amnion reveals its close approximation to the germ disc, and if one is involved, so must be the other. Moreover the extremely early period of the finding of deformities, for example, long before limbs appear as such, seems to aid in refuting such a theory.

5. Variation in organ performance. The example offered here is that even in extremely goitrous areas not everyone suffers from goiter. The specificity of keloids is another individual variation.

6. Tissue vulnerability. Experiments in the laboratory have shown one strain of rats to be more susceptible to ticks than another and also that the first strain's lack of resistance to ticks can be raised by breeding.

Streeter offers further interpretation of the normal disparity inherent in the germ plasma and hereditarily transmitted. A given tissue may have abnormally great or deficient growth potency. The damage done depends upon the part and area involved. There seems to be a predilection for mesenchymal and particularly subcutaneous connective tissue involvement.

M. Jansen supports the amnion theory by a division of fetal life into three stages. During the middle one lasting from the fourth week to the fifth month the amnion envelops the fetus but has not fused with the chorion. Moreover the hydrostatic pressure is raised. Hence in this second stage smallness of the amniotic sac and consequent rise of hydrostatic pressure in it will cause the blood of the fetus to flow into the placenta until, in the latter the widening of the blood vessels has led to a like rise in pressure. The fetus then suffers from famine.

This may cause death and fetal expulsion. If not death, then the fetus will lose its power of growth—it will be dwarfed. At the end of the second stage the amnion may cause undue flexion of the hip. It would seem that Jansen's theory would be more applicable to bone deformities.

Hellner experimentally produced amputation by tying cords about the extremities of rabbits' embryos while in utero. His conclusions are that the responsibility must be traced to the gene if

it is amniotic in origin there is only an occasional end defect

CONCLUSIONS

1 A brief summary of some of the current theories of congenital deformities has been presented

2 It is apparent that both genetic and environmental forces may lead to malformations of the same type, to malformations of identical or similar anatomical appearance. This implies that identical malformation may be hereditary in one case and nonhereditary in another. Warkany

3 The prevention of deformities still requires a great deal of study but much assistance and both encouragement and warning can be offered parents with a congenitally malformed child

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Xeroderma Pigmentosum with Affection of the Eye. JOHAN SAKR. *Brit J Ophth* 1948 32 398.

Xeroderma pigmentosum is a rare hereditary actinic dermatosis which is characterized by brownish maculae sensitive to sunlight and the development of multiple malignant cutaneous tumors. Ocular complications include ectropion pigmented conjunctival tumors telangiectasis and papillomas of the limbus and cornea proper.

Three cases of xeroderma pigmentosum with ocular involvement are reported. The first case was that of a girl 17 years old with freckles on the face and extremities, who developed a pigmented tumor at the right temporal limbus resembling a pterygium. Excision was followed in 2 years by a recurrence which disappeared entirely with local x-ray therapy. Eight years after the pterygium was first diagnosed she developed a basal cell carcinoma of the right cheek which responded to radium treatment. Malignant tumors continued to form but were controlled by radium or x-ray therapy. This patient's brother age 32 had brown spots on his face and extremities was sensitive to sunlight, and suffered from photophobia. Since the age of 27 years he had had many malignant tumors and ulcers of the skin which had been treated with roentgen rays or radium with good results. The right eye showed a red spot close to the limbus which consisted of localized dilations of episcleral vessels and was considered part of the disease.

The third patient, a 10 year old male had a bluish white hard insensitive cauliflowerlike tumor at the nasal limbus of the left eye. Eight years later the mass covered the eye and the face showed large and small telangiectases nevi and angiomas. Treatment was refused and subsequently both eyes had to be enucleated because of pain the new growths spread gradually over the face and the patient died at the age of 21 years.

The author emphasizes the fact that xeroderma pigmentosum must be kept in mind in cases of seemingly benign ocular tumors appearing in conjunction with pigmented spots in the skin.

FRANK W. NEWELL, M.D.

Ocular Lesions Following Atomic Bombing. JONES J. *Fuchs. Am J Ophth* 1948 31 137.

The author was able to study numerous cases in which there were ocular lesions following atomic bombing. The lesions resulting from the explosion of the atomic bomb may be divided into three categories: (1) mechanical injuries from the blast (2) thermal injury from long wave energy and (3) radi-

ational injury from gamma rays and neutrons emitted at the time of detonation.

The mechanical injuries differed in no way from those produced by other explosive agents.

The thermal injuries from long wave energy were evidenced by pigmented flash burns and copper colored burns of the side facing the explosion. Some of these burns involved the cornea and produced red inflamed lacrimating eyeballs.

The ocular lesions associated with radiation were limited to the retina as far as clinical features were concerned and were found in 46 cases. The following types of hemorrhage were observed: (1) flame shaped hemorrhages (2) preretinal hemorrhages (3) Roth type hemorrhages (4) vitreous hemorrhages. Case histories are cited.

In conclusion it is pointed out that the transient nature of the condition prohibits any definite conclusions as to the pathogenesis of these lesions. It is the author's opinion that exudative lesions represent the milder involvement. It seems safe to conclude that the ocular lesions here described are directly related to the deficiency in blood elements and in no way directly related to the action of radiant energy on the eye.

J. WOODHULL OVERKON, M.D.

Vertical Anomalies. Presentation of Vertical Anomalies in 100 Cases Studied. BEULAH CUSIDMAN and LOUIS SARRO. *Q. Bull. Northwest Univ. M. School* 1948 22 17.

The authors present a study of 100 cases of vertical anomalies associated with lateral deviations. The etiology of vertical anomalies is discussed. The necessity for a complete diagnosis of the squint is pointed out, for the success of treatment, whether surgical or nonsurgical is dependent upon it.

The summary and conclusions of White and Brown who discussed the problem of vertical anomalies before the American Academy of Ophthalmology and Otolaryngology in 1938 are given.

In 71 of the 100 patients studied the vertical anomaly was so definite that surgery was necessary on the elevators or depressors. The majority of the vertical anomalies occurred in patients with convergence excess among a group of 48 patients 44 had vertical anomalies.

Thirteen patients with convergence insufficiency required surgery to the medial recti. In 7 of these vertical anomalies were present.

Vertical anomalies were found in 8 of 21 patients whose condition was diagnosed as divergence excess.

Of 19 patients in whom a diagnosis of divergence insufficiency was made 12 had vertical anomalies.

Simple vertical anomalies were present in 5 patients without the association of any center anomaly.

In conclusion the authors state that the diagnosis of any ocular muscle imbalance should always include the individual muscle anomaly as well as the type of center anomaly. Vertical anomalies should be suspected in every patient with an ocular muscle imbalance.

J. WOODRILL OVERSTON, M.D.

Experimental Corneal Transplantation. HARRERT M. KATZ and P. K. KOO. *Am J Ophth.*, 1948, 31, 7.

Although corneal transplantation has been studied since 1824, the biologic process that takes place between host and graft remains as yet incompletely understood. The authors summarize the literature on corneal transplantation both human and experimental, and discuss the evidence in favor of true healing versus replacement of the graft.

Experimental studies are presented with sections showing normal healing as well as operative complications. It is pointed out that corneal tissue is unique in its properties of transplantability.

The material presented was obtained from a study of over 200 corneal transplantations on rabbits, and over 100 histologic sections of operated eyes. Several important factors in corneal transplantation have been learned from the study and others have been inferred. In order for the corneal graft to remain clear and heal properly it must be obtained from fresh, viable cornea of the same species. The epithelium and probably the endothelium are replaced in the graft by the appropriate cell layers from the host. The healing that takes place at the stroma level involves the ingrowth of a great number of fibroblasts or keratoblasts from the host. The authors are not sure as to the fate of the stroma cells in the central part of the graft but in view of the fact that bodily tissue cells are normally replaced from time to time in the course of their metabolism they believe that this also occurs in the cornea and that, over a period of years, the stroma cells replace the donor cells so that eventually the host takes over. It is pointed out that the graft must be surrounded by a sufficient number of normal corneal cells and the transplanted cornea must be sufficiently viable so that a large portion of its structure does not need to be replaced rapidly. When rapid replacement occurs the resultant membrane is translucent.

Anterior synechias are very prejudicial to the success of the graft. They form the basis for vascularization, fibrosis, glaucoma and iridocyclitis. Anterior synechias can be avoided by careful coaptation of the margins of the wound and thorough dilation of the pupil.

The authors do not agree entirely with either extreme point of view as to the biological process taking place in corneal transplantation but do agree in part with each.

The authors believe that in successful cases the cellular elements of the transplant are replaced by the host and that the intercellular structures of the graft are accepted and persist.

J. WOODRILL OVERSTON, M.D.

Results of Surgical Treatment of Congenital Cataract. WILIAM COUNCILMAN OWENS and WILLIAM F. HUGHES, JR. *Arch. Ophth.* Chic., 1948, 39: 339.

Criteria for estimating the visual prognosis in congenital cataract were derived from an analysis of 331 eyes operated at the Wilmer Ophthalmological Institute, Baltimore, in the period from 1925 to 1943. Associated ocular defects such as nystagmus, strabismus, and microphthalmos were discovered in some what over half the patients. In the group of patients who were free from such defects the best visual results occurred in those operated upon at 3½ years of age or later. Of these 70 per cent secured satisfactory vision (20/70 or better) and 16 per cent were considered failures (acuity of less than 20/200). When the cataracts in otherwise normal eyes were operated upon before 3½ years of age, only 9 per cent of patients secured satisfactory vision and failures occurred in 36 per cent. In contrast, 14 per cent of the eyes with associated defects, when operated upon at 3½ years of age or later, secured satisfactory vision and 35 per cent secured inadequate vision but among infants operated upon under 3½ years of age no case of satisfactory vision resulted.

Adequate vision followed linear extraction when done primarily or shortly after discission, in 76 per cent and 78 per cent of the eyes respectively, discissions alone gave a comparable result in only 29 per cent. Secondary operations to clear the pupillary space were required much less often in the cases of linear extraction. The maturity of the cataract bore no relation to the complications or visual result.

With the best modern technique the prognosis for good vision in senile cataract is 95 per cent. The poorer results in congenital cataract are attributable to either gross or obscure associated ocular defects.

In the discussion, Cordes maintained the view that if the opacities are sufficiently dense to interfere with fixation the first eye should be operated upon at the age of 6 months. He agreed that linear extraction was the operation of choice irrespective of the age of the child.

JAMES E. LUNDENSON, M.D.

Vascular Fundus Disease with Especial Reference to the Classification of Gifford and MacPherson. IRVING FURTHMAYER. *Q. Bull. Northwest. Univ. M. School* 1948, 74.

The author presents the Gifford and MacPherson tentative classification of vascular fundus disease (1940) and discusses ways in which it might be improved. The classification of fundus conditions seen in patients with cardiovascular renal disease was proposed for the purpose of teaching those unfamiliar with vascular fundus disease to orient themselves and make headway in a subject which would otherwise totally confuse them.

There are five groups in the classification. Groups 1 and 2 show the localized vascular changes associated with arteriosclerosis. Groups 3, 4 and 5 show the various stages of diffuse arteriolar constriction. The chief vessel changes which may be observed in patients with arteriosclerosis are given.

The author points out that it is difficult to decide on and enumerate the findings which serve to differentiate one condition from the other. It is this latter ability which is absolutely essential in teaching and it is often the basis for the distinction between a good textbook and a poor textbook, a good teacher and a poor teacher. It is stated that certain inconsistencies become less apparent if subgroups are added to groups 3 and 4 and if groups 1 and 2 are reserved for senile sclerosis without hypertension and retinal arteriosclerosis with hypertension.

In conclusion the author points out that the classification of Gifford and MacPherson fulfills the purpose for which it was proposed and its further use is recommended.

J. WOODHULL OVERTON M.D.

Melanomas of the Uveal Tract ROBERT E. KENNEDY
Am J Ophth 1948 31 159

Cysts occurring in malignant melanomas of the uveal tract are chiefly of pathological interest but may in themselves present a clinical picture with a complicated diagnostic problem.

When cysts occur in ciliary body melanomas which extend behind the lens, and in melanomas of the choroid and iris which can be readily observed there is no additional diagnostic problem. However malignant melanomas projecting into the posterior chamber from the posterior surface of the iris or from the ciliary body may be difficult to differentiate from simple cysts. This diagnostic difficulty may be enhanced when malignant melanomas in this position become cystic. Reports have appeared in the literature of at least 8 cases of benign cysts of the posterior chamber in which the eyes have been enucleated following the diagnosis of malignant tumor, hence the differential diagnosis between cystic melanoma and a benign uveal cyst may be difficult. The author reports several cases to illustrate this problem.

The determination of translucency and the diagnostic puncture may differentiate a solid and cystic mass in the posterior chamber but cannot differentiate a benign and malignant cystic mass thus they are unreliable diagnostic procedures.

When possible, iridectomy and microscopic examination should be used to diagnose such lesions when their diagnosis is in doubt.

Large cystic spaces in malignant melanomas arise from the growth of small focal areas of tumor necrosis which are the result of inadequate nutrition.

The cystic manifestation is present in about 8 per cent of all malignant melanomas of the uvea has no predilection for the site in the uvea or the cell type and has no apparent effect on the prognosis of malignant melanomas.

J. WOODHULL OVERTON M.D.

Review of 100 Cases of Retinal Detachment RUTH APPELZAY and D. K. PISCHEL. *Am J Ophth* 1948 31 706

The authors analyze 100 consecutive cases of idiopathic retinal detachment in which electrodiathermy was employed. They point out a number of important features of retinal detachment work

The most common symptom was a shadow or curtain coming across the eye (44 patients), black spots or floaters (31) flashes of light (14) and blurred vision (39).

Retinal tears were found in 88 per cent of the cases. The horseshoe-shaped tear was most common (58 per cent of the cases). There were also round holes (33 per cent) macular holes (2 per cent) linear and oval holes (7 per cent) irregular rents (5 per cent) crescent-shaped (3 per cent) and oral disinsertions (10 per cent). The following types of detachments were found: 35 per cent were bullous, 33 per cent were flat, 32 per cent were bullous and flat, and 21 retinas were totally detached (15 of these were cured).

Because successful reattachment depends on closure or sealing of one tear or of several tears careful localization of retinal tears cannot be overemphasized. The site of a tear is not necessarily at the area of greatest detachment; it may be found in a flat or in an apparently attached area of the retina. In some cases a tear may become visible only when the retina settles back following bed rest; in other cases previously visible tears become displaced into the periphery or do not stand out because of the lack of color contrast.

The history and repeated examination may actually reveal or serve as a clue to the possible location of a tear.

Tears are localized with the hand perimeter as to arc and meridian. An arc of 50 degrees represents a point 15 mm posterior to the limbus and each 5 degrees of arc is equal to approximately 1 mm.

Preoperative management consists of bandaging of both eyes and absolute bed rest for 4 or 5 days in a position that is most dependent for the retinal tear. In half the cases the retina settled back but no change was noted in 15 cases and in 3 cases the detachment increased.

Surgical management. Under local avertin anesthesia the horizontal meridian of the eye was marked at the limbus prior to the retrobulbar injection. The conjunctiva was incised 8 mm. from the limbus and with Tenon's capsule was separated from the sclera posteriorly. The tear was localized with the ophthalmoscope and an Arruga spoon and gentian violet were used to mark on the scleral surface the position of the tear. Partial penetrating Pischel electrodes and the Rose Walker diathermy machine were used employing 50 milliamperes for 2 to 3 seconds. Two or 3 spots of diathermy were placed from 1 to 2 mm behind the localized tear and the fundus was examined to ascertain that these were in actual relation to the tear. If the spots were not visible as in cases of elevation of the retina a Pischel pin was inserted over the localized area on the sclera to serve as a guide. A double row of coagulations was placed about the tear coming up to the ora serrata (8 mm in emmetropes and 9 mm in high myopes). Cystic areas were included. Pischel pins (usually 9 to 12) were inserted within the loop of diathermy barrage for drainage. If no drainage was obtained from the pin openings perforating electrodes or trephine

openings were used. In 10 cases air was injected into the vitreous chamber to push the retina toward the choroid.

Postoperatively the patients were kept in bed with binocular bandages for 3 weeks. The first of daily dressings was done on the second postoperative day and stitches were removed on the seventh to tenth day when the fundus was examined. After 14 days, peephole glasses were substituted for bandages and worn for an additional 6 weeks with the patient's activities limited.

It is concluded that the smaller the extent of the detachment the better the chance for surgical success and that retinal detachment should be treated as an emergency with immediate hospitalization and operation as soon as the retina has settled back to the normal position. On the basis of permanent reattachment regardless of the resultant visual acuity or of the peripheral field 86 per cent of the patients were cured. (A second diathermy operation to obtain reattachment was done on 15 eyes in 10 cases the operation was successful.)

JOSUUA ZUCKERMAN, M.D.

EAR

Surgery of Aural Suppuration after Radical Mastoidectomy J A HARRMAN. *J Lar Otol Lond.*, 1918, 6: 435.

The article deals with the surgical management of aural suppuration following radical and modified radical mastoidectomy. The pathological processes causing such suppurations are commonly located around the middle ear ossicle of the eustachian tube in the hypotympanum, the anterior superior part of the attic, the incus or malleus, the petrous bone around the semicircular canals, and, rarely in the petrous apex. Surgical exposure and removal of the hypotympanic suppurations are accomplished by an anterior inferior endaural incision at the osteocartilaginous junction. Skin and periosteum are elevated and removed and the bone of this portion of the bony external canal is removed. Granulations and infected cells in the hypotympanum are exenterated with the curet. Possible complications such as injury to the facial nerve, jugular bulb, internal carotid artery and entrance into the mandibular fossa are discussed. Safeguards against them are mentioned. The lining of the eustachian tube is curetted. Occasionally when eustachian tube suppuration continues in spite of this procedure, a third operation is carried out in which the eustachian tube is curetted and then filled with a strip of temporal muscle after the method of Wittmack.

Foci of suppuration in the upper part of the middle ear and the mastoid part of radical mastoidectomy cavities are reached by an incision along the anterior superior portion of the external auditory meatus which extends upward just in front of the anterior part of the helix. Skin and periosteum are elevated. The diseased areas of the bone are exenterated with curets, gouge or burr. Extensive surgery of the

petrous portion of the temporal bone is possible through this incision as is also surgery of the mastoid tip although this is much more easily approached by the postauricular route.

Possible complications such as injury to an already exposed dura mater are discussed. Postoperative care of the patient including the use of a widely bacteriostatic compound containing penicillin, flavazole, phenoxetol and urea is discussed.

The author offers a series of 15 cases in which he reports practically no postoperative discomfort.

WILLIAM K. WHEAT, M.D.

MOUTH

Tumors of Salivary-Gland Origin GRANTLEY W TAYLOR and GERALD G GARCELON. *N England J M* 1948, 38: 766.

The authors summarize their experience with tumors of salivary-gland origin observed at the Massachusetts General Hospital, Boston, from 1930 to 1941 inclusive and at the Pondville State Cancer Hospital, from 1927 to 1941 inclusive.

Diagnosis. Usually the patient presents a symptomless tumor in the submaxillary or parotid region, which is discovered accidentally or because some fullness or swelling is noted.

The essential differences between carcinoma and mixed tumor are summarized as follows:

	Mixed tumor	Carcinoma
Median age of patients	30 to 40 years	50 to 60 years
Median duration of tumor	More than 3 years	Less than 1 year
Tumor of hard consistency	30 per cent	80 per cent
Movable tumor	80 per cent	15 per cent
Enlargement of cervical lymph nodes	3 per cent	47 per cent
Primary facial nerve palsy	0 per cent	25 per cent
Remote metastases	0 per cent	25 per cent

It is evident from these data that in many cases the diagnosis on clinical evidence is ambiguous and that exploration must be done. At the time of operation the discovery of lack of definition of the limits of the tumor, the persistence of fixation as the operation progresses and the apparent implication of the branches of the facial nerve in the tumor itself all argue for the probable diagnosis of cancer. In cases of doubt it is necessary to resort to immediate pathological examination.

Treatment of mixed tumor. Simple enucleation of these tumors destroys the best chance of effecting a cure. A radical excision of the gland with visualization and protection of the facial nerve (Adson-Ott operation) gave the best results. Eighty-five patients with primary tumors were treated by surgery of

these 8 developed recurrences and 6 had some facial paralysis. Of 19 patients with recurrent tumors submitted to operation 3 had already suffered injury to the facial nerve. Four patients with secondary tumors developed later recurrence and an additional patient suffered facial nerve injury. Fifteen primary tumors and 10 recurrent tumors were treated by the Adson-Ott operation. There were no recurrences among the patients with primary tumors, but there were 3 recurrences and 1 case of facial paralysis among the recurrent cases. Those patients with local recurrences were successfully treated by second or third operations.

The treatment of carcinoma is unsatisfactory and the method of treatment depends upon the stage of the disease. In early cases recognized by the pathologist and not the surgeon nothing more is done if the Adson-Ott operation has been performed. If carcinoma is recognized at surgery the Adson-Ott operation is indicated or if the facial nerve is involved, more radical measures combined with a radical neck dissection are indicated.

Tumors presenting wide local fixation inoperable metastasis, or remote dissemination when first seen are treated by surgery or roentgen therapy or both as indicated.

A 12.5 per cent rate of cure was all that could be effected in the 40 patients who were operated on.

Radiation was not an effective treatment for carcinoma.

NECK

Studies of the Thyroid Gland of Parturients and Newborn Infants in Southern Finland (Helsinki) VILHO HILLESMAA. *Acta obst gyn scand* 1945 28 Supp. 1

For the purpose of studying the goiter situation among mothers and newborn infants in southern Finland, 1,000 consecutive parturients and their 1,015 children (15 twin pregnancies) were examined. The material also includes 8 thyroids of mothers who died during delivery and 47 thyroids of infants who were examined after death.

Among 1,000 parturients goiter was found in 141 cases (14.1%) and 121 patients (85.8% of the 141 cases) were cognizant of their thyroid enlargement. The goiters were small or medium sized. In 11 cases (7.8%) the goiter had first appeared during a pregnancy and in 39 cases (27.7%) a pre-existing goiter was further enlarged during pregnancy. Pressure symptoms in the neck were present in 35 cases (24.8%) and were mild in degree. There was a family history of goiter in 48.9% of the goitrous mothers as compared to 14 per cent of the nongoitrous mothers. Thirty-nine per cent of the goitrous mothers had lived for a long time in the regions where goiter is most prevalent in Finland.

With the advance of age and an increase in the number of deliveries goiter and nodules of the thyroid gland appeared more frequently. Palpable nodules of the thyroid gland were present in 23.4% of

the 1,000 parturients. The rate of incidence of nodules was 64.5 per cent in the cases of goiter and 16.6 per cent in thyroid of normal size. Thyrotoxicosis was found in 9.2 per cent of the goitrous mothers. In about half of the cases pregnancy aggravated the symptoms and in one case improvement was observed.

Prior to admission to the obstetric clinic, 13 mothers had been submitted to operation for goiter: 11 because of thyrotoxicosis, 1 mother because of pressure symptoms and 1 solely for cosmetic reasons.

Postmortem examinations were carried out in 8 of the mothers. There were 4 definite cases of goiter, 2 borderline cases and 2 thyroids of normal size. Nodules were noted in all of the goiter cases in one borderline case and in one of the two normal sized glands. Histologically there was evidence of hyperfunction in half of the 8 cases.

Among the 1,015 newborn there were 139 cases of goiter, the goiters generally being small. Symptoms that have been reported in connection with severe endemic goiter such as thyrogenous constitutional weakness, shortness of stature, subnormal weight, or congenital cardiac disease were not noted in the author's series. There was a 25 per cent incidence of goiter among 23 full term infants that came to autopsy. The histologic picture in these infants was characterized by small follicles and an abundance of epithelium, follicles of medium size were also found. The epithelium was cuboidal or cylindrical. There was but little colloid. The histologic picture was qualitatively the same in the congenital goiter as that of normal sized thyroids.

Congenital goiter occurred in 35 (24.5%) of the infants of the goitrous mothers and in 104 (11.9%) of the infants of the nongoitrous mothers.

From the obstetrical point of view goiter caused no complications in the mother or in the infant.

EARL O. LATIMER, M.D.

Chronic Thyroiditis. SAMUEL F. MARSHALL, WILLIAM A. MEISNER, and DELBERT C. SMITH. *N England J Med*, 1948, 238: 758.

Chronic thyroiditis as evidenced by degenerative and fibrotic changes in the thyroid gland is not a common disease. Clinically it is important to recognize this condition because its firmness, adherence, and increase in size may be mistaken for a malignant condition of the thyroid.

This report from the Lahey Clinic covers an 18 year period during which 187 cases of thyroiditis were encountered in the pathological examination of the specimens from approximately 25,000 patients requiring thyroidectomy. This represents an incidence of 0.75 per cent.

The diagnosis can be made clinically at times but too frequently biopsy or resection of the lobe is necessary for a diagnosis. A correct preoperative diagnosis of thyroiditis in the group of 187 cases was made in only 44 patients or 23 per cent. Operation is demanded when even the slightest suspicion of a malignant lesion exists and progressive enlargement

or constrictive symptoms occurring in a previously clinically recognized thyroditis may also require surgical interference at some time after the initial diagnosis has been established.

The authors divided their cases into three groups that could be distinguished clinically and pathologically.

Group I consisted of 41 glands showing a reaction that appeared to be due to infection. It is well known that acute infections of the thyroid occur but as such glands are not removed surgically no such cases are in this series. However 18 glands showing subacute inflammatory changes were encountered. There was moderate fibrosis with numerous inflammatory cells chiefly polymorphonuclear cells often centered in acini. Such acini usually showed degeneration and spillage of colloid with some foreign body giant cell reaction.

In the chronic stage as seen in 18 other cases the polymorphonuclear leukocytes had largely disappeared but numerous foreign body giant cells reacting to colloid were still present. Also scattered throughout the stroma were numerous lymphocytes and plasma cells.

The remaining cases in this group represented the healed stage in which fibrotic changes were predominant. Foreign-body giant cells were usually absent and other inflammatory cells were few in number.

In not one of the stages in this group were epithelial changes characteristic, the remaining epithelium was normal. Grossly all these glands were firm, fibrotic, and often gray or white. The capsules in most specimens were adherent to both the thyroid and adjacent structure.

Group II was composed of 78 thyroid glands which were generally designated as Hashimoto's stromas or struma lymphomatosa. Stromal infiltration with lymphocytes and the formation of numerous secondary lymph follicles. The specimens also showed atrophy and marked acidophilia of the epithelium. Grossly the specimens averaged 100 gm. for two lobes and had a rubbery consistency. The changes were diffuse and homogeneous. The capsules were preserved with no suggestion of adherence.

Group III consisted of a conglomerate group including thyroditis from several causes. Grossly the specimens showed little that was characteristic. Microscopically they showed the basic stromal and epithelial changes common to all injuries of the thyroid gland, but the changes were so mild that a further classification was not possible. This group was simply designated chronic thyroditis nonspecific and included 68 cases.

Symptoms of all these patients were more or less similar. Goiter or enlargement of the neck was the most common complaint. Local symptoms as pressure, breathing difficulties, choking sensation and difficulty in swallowing, were less common. Neck discomfort was outstanding in the cases of infection thyroditis (Group I). The average duration of symptoms was a year.

Diagnosis is established by an increased size of the gland, which is bilateral and symmetrical (occasionally Riedel's struma is unilateral). The anatomic outline is maintained. In Riedel's struma the firmness is marked and adherence to surrounding structures is noted. Struma lymphomatosa is firm, but more elastic, and is not adherent to the surrounding structures. Frequently the differentiation from cancer can be made clinically but at times biopsy or resection will have to be performed.

Treatment is often unnecessary when the diagnosis can be made but the patients should be observed for subsequent compression of the trachea.

Partial resection or resection of the isthmus is the treatment of choice when tracheal constriction is to be relieved.

Radical removal of the gland is to be avoided lest the parathyroids or recurrent laryngeal nerves be damaged when the gland is indurated (Group I).

In struma lymphomatosa (Group II), a partial bilateral thyroidectomy is the best procedure.

In Group III a resection of the isthmus usually suffices.

Most of these patients need desiccated thyroid postoperatively. EDWARD R. DOUGLASS, M.D.

Notes on Twenty Year Observations of Goiter in the Surgical Clinic of Geneva (Remarques sur 20 années d'observations de goitres à la clinique chirurgicale de Genève) EDOUARD WITTEG. *Helv. chir. acta*, 943, 5: 00.

The present article is based on a study of 594 patients with goiter 356 of whom were operated upon. The total number of surgical interventions was 592.

Of the 594 patients 483 (81.3%) were women. The youngest patient was 13 and the oldest was 85 years of age. The outcome (592 operations) was fatal in 19 cases, a mortality of 4.9 per cent. Sixty two per cent of fatalities were among patients with hyperthyroidism and 38 per cent were among patients with nontoxic goiter. In the last 10 years the mortality fell to 3.7 per cent. Sometimes the ligation of one or several thyroid arteries preceded the subtotal thyroidectomy in patients with a high metabolic rate.

Of the 594 patients 308 (51.8%) presented clinical signs of hyperthyroidism.

In Geneva, the relative incidence of hyperthyroidism (30.1%) is higher than in other parts of Switzerland where the incidence is from 4 to 12 per cent. In 1 case out of 6 the clinical symptoms, the metabolic rate and the microscopic picture correspond, one to another. Such contradictions may be explained by the fact that in some instances the patients cease producing thyroxine, because of the secretion of an unknown substance by the organism. This substance probably has an effect similar to that of thiocyanate on goiters, or alloxan on hypoglycemia. Moreover, in some cases metabolic disturbances may be created by an unrecognized compression of the respiratory tract. In such cases a titration of iodine in the blood may establish the correct diagnosis.

JOSEPH N. KATZ, M.D.

SURGERY OF THE HEAD AND NECK

A New Method of Transverse Pharyngotomy A.
Réthi. *J Lar Otol.*, Lond. 1948, 62 440.

The author states that transverse pharyngotomy is indicated whenever it is necessary to inspect the mesopharynx or hypopharynx, and for the removal of tumors which are inaccessible or inoperable through the mouth such as a lingual thyroid. The disadvantages of subhyoid or of suprahyoid pharyngotomy are that the area on the other side of the hyoid bone cannot be readily visualized also the sutures tend to pull out because of muscle strain inspiratory strain and cough frequently resulting in a downward displacement of the larynx with danger of asphyxiation pneumonia.

Réthi's method of transverse pharyngotomy does not have any of these disadvantages. It is done under local anesthesia with preliminary inferior tracheotomy. A transverse incision is made along the hyoid bone and the platysma muscle is severed the hyoid bone is uncovered the submandibular gland and the hypoglossal nerve are pushed upward 1 cm. above the hyoid margin, the strap muscles are severed but only below the body of the hyoid bone the thyrohyoid ligament is cut and the pharyngeal mucosa is exposed but not opened above the hyoid the hyoglossus and constrictor muscles adherent to the greater cornu are severed, the tendon of the digastric and stylohyoid muscles are disconnected from the periosteum and the pharyngeal mucosa is exposed. From these points vertical incisions are made connecting with the lateral boundaries of the lower incision the hyoid bone is sawed through in each incision the pharyngeal mucosa is opened along the entire line of these incisions. After the intra-pharyngeal operation the mucosa is sutured with

Fig 1 (Réthi) Muscle and bone suture. Greater cornua fastened toward larynx by unsevered soft parts. The strong tongue muscles have been left in their attachment to hyoid bone. The bone suture prevents wound from separation.

fine catgut the hyoid bone is united with wire the thyrohyoid ligament is sutured with catgut, as are the muscles of the tongue and the strap muscles and the skin is closed with clips. Thin glass tube drains are placed under the muscles on both sides, and 2 days later they are replaced with gauze strips. Uneventful primary union almost always occurs.

Two cases of lingual thyroid are presented. One patient was operated upon by the new method to show the difference in the postoperative course. The method of preventing blood from entering the larynx during the operation is described. A tampon is anchored in the larynx and pulled down into it by a double silk thread coming out through the tracheotomy. A Bellocque sound is used in introducing the

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Lymphatic Connections of the Subarachnoid Space. E. J. FIELDS and J. B. BRIDLEY *Bull. M. J.* 1948, 67

The authors present an experimental study of lymphatic connections of the subarachnoid space with special reference to the pathogenesis of poliomyelitis. Particles of India ink introduced into the cranial subarachnoid space of the living rabbit tend to accumulate at certain outflow points in the cervical and lumbar regions of the spinal cord.

The prevertebral lymph nodes are considered to be the regional nodes for the spinal arachnoid space. In the rabbit, the authors show that particulate matter introduced anywhere in the subarachnoid space accumulates largely in the region of the lumbosacral root ganglia in from 6 to 12 hours. Lesser amounts collect in the cranial region along the sheaths of the olfactory filaments and through the jugular foramen. In 24 hours the India ink is cleared from the subarachnoid space, discounting that small amount taken by phagocytosis.

In other experiments the lymphatic pathways were filled in a retrograde manner from the mesenteric and prevertebral lymph nodes after preliminary ligation of the thoracic duct. According to the authors, the possibility of retrograde passage of the polio virus to the lumbar region of the spinal cord must be considered. Results of experimental poliomyelitis are discussed in relation to anatomical observations of the lymphatic pathways from the subarachnoid space in the rabbit.

JOHN L. BELL, M.D.

The Treatment of Subdural Hematoma (Zur Behandlung des subduralen Hämatoms). P. SÖDERBERG. *Pharmaz. Zentr. woch. Nachr.* 1948, 73, 85.

The author states that during the past few years he has found cerebral arteriography with per-abrodil to be of great value in the diagnosis of subdural hemorrhages as well as of brain tumors. He points out that practically one-third of all cases of subdural hematoma are bilateral and that arteriography or trephination should be performed in all doubtful cases.

The advantages and the disadvantages of removal of the membrane of a chronic subdural hemorrhage are discussed. It is emphasized that the important factor is the re-expansion of the brain after the clot has been removed and that extirpation of the membrane is not essential and may be even harmful. In those cases in which expansion of the hemisphere does not occur there is frequently a terminal central hyperthermia of 40 degrees or more which occurs about 8 to 10 days postoperatively. To prevent this, novocain cervical sympathetic block is advocated by the author.

A case is presented to illustrate this valuable aid in the treatment of such patients. A 45 year old man had suffered a fall 4 months previous to admission to the hospital and, during the 14 days prior to being seen by the author had developed aphasia, right hemiparesis, disorientation and unconsciousness. There was a dilated left pupil. Arteriography confirmed the diagnosis of a left subdural hematoma. A large osteoplastic flap was turned and the hematoma was evacuated, the membrane being left *in situ*. Immediately after the operation the patient was able to talk in monosyllables, but lay in bed staring directly ahead of him without movement of his extremities. His condition did not further improve and he developed a central hyperthermia. Another x-ray examination after operation showed a layer of air over the left hemisphere, since re-expansion of the brain had not occurred. All attempts made to inflate the hemisphere by the rectal, subcutaneous and intravenous introduction of saline solution were of no avail. The author quotes Coleman as saying that the failure of re-expansion of the brain is the most severe complication observed in these cases.

The clinical syndrome of central hyperthermia and constant stare suggested a disturbance of the central regulating mechanism of the diencephalon. The author states that he had seen similar patterns in cerebral endarteritis obliterans and was cognizant of the part played by the autonomic nervous system in relation to it. On the seventh postoperative day he performed a successful cervical sympathetic block with novocain. The following morning the patient greeted him for the first time, the hyperthermia vanished and the motor power in the paretic side began to return. Along with the clinical improvement there was a disappearance of the layer of air previously noted. The patient made an uneventful recovery.

The author is convinced that the improvement in the patient's course followed the procain block of the cervical sympathetic system, which resulted in rapid and complete re-expansion of the left hemisphere. He does not think that this is merely a vasomotor effect, but from his observations on other cases he believes that in addition to the vasomotor component there is a direct response of the central regulatory mechanisms which exercise their effect on the nuclei of the diencephalon and possibly exert some influence on the production of the cerebrospinal fluid.

RICHARD C. SCHENKEL, M.D.

SPINAL CORD AND ITS COVERINGS

A Case of Vertebral Hemangioma with Paraplegia (Su di un caso di emangioma vert. brale con paraplegia). PARIDE STEFANELLI. *A. n. Ist. esp. Aquisani.* 1946-47, 1, 375.

A 17-year-old boy suffered an attack of heaviness and numbness of the lower extremities which lasted

about a month. Two years later the symptoms reappeared and in the course of 2 months eventuated in symptoms of spastic paraparesis with accentuated reflexes and a bilateral hypaesthesia extending downward from the level of the seventh dorsal segment and becoming ever more pronounced distally. There was some tenderness in the paravertebral fossa especially on the right side. The muscles were not wasted and there was no other evidence of trophic disturbance. Spinal puncture and examination of the spinal fluid obtained disclosed findings consistent with block of the spinal canal which neurologic study placed between the fifth and sixth dorsal vertebrae (seventh medullary segment). Roentgenologic examination placed in evidence the typical longitudinal striations of alternating osteoporosis and eburnation in the fifth dorsal vertebra characteristic of vertebral hemangioma. The diagnosis was massive extramedullary compression at the level of the seventh medullary segment caused in all probability by vertebral angioma.

The operation of laminectomy resulted in severe bleeding which was especially severe at the level of the fifth dorsal vertebra and on the right side. The laminectomy was completed first on the fourth and sixth dorsal vertebrae and then on the fifth vertebra the bleeding being controlled by electrocoagulation and by insertions. Here the tumor was found to be attached to the vertebral peduncle on the right side and the whole was removed together with the peduncle itself. The compression of the cord was caused by the tumor which had pushed the cord forward and to the left.

Histologic examination disclosed the nature of the tumor as a capillary angioma. Forty five days later the patient was able to walk about unassisted and 5 months later the neurologic examination was completely negative. Before the patient was discharged 5,000 roentgens were given over the involved vertebra. The patient was seen 5 years later and at this time the lesion was still neurologically silent however roentgen examination disclosed that the lesion in the body of the vertebra had made further progress. The body of the vertebra was now dilated—blown up like a bottle—and the intervertebral space between the fourth and fifth dorsal vertebrae was narrowed probably as a result of the operation.

The author believes that in these cases complicated by a paraplegia surgical intervention is indicated and that roentgen therapy should be reserved for the uncomplicated cases.

JOHN W. BRENNAN, M.D.

PERIPHERAL NERVES

The Pathology of Peripheral Nerve Injuries. WOOD HAYMAKER. *Mil Surgeon* 1948, 102: 448.

The author does not believe that it is wise to perform immediate definitive end-to-end sutures of nerves which have been severed in gunshot wounds. He maintains that the contusion is greater than is at first apparent and that the contused zone of the

nerve is well demarcated from the intact zone about 3 weeks after the injury. Further arguments for delaying suture 3 weeks are that at this time the epineurium in the region of the injury has thickened and gained in tensile strength so that it holds a suture more adequately and the Schwann tubules of the distal segment are wide open to receive regenerating fibers. In a severed nerve the newly formed axons grow rapidly down the Schwann tubules. When they enter the contused region of the proximal segment in which the fascicular arrangement has been lost and in which the connective tissue is still in the process of forming a dense scar the fibers become grouped together in aberrant fascicles and twist about, forming a large bulbous mass the proximal neuroma. Since the nerve still has remarkable regenerative powers weeks after the injury the author does not believe that downward growth should be hampered by scar tissue which could be resected after the extent of contusion has declared itself. After a period of 2 months the Schwann tubules begin to lose their patency and downgrowth of new axons becomes increasingly more difficult. When regenerating axons reach a muscle which has been denervated for only a short period of time they re-enter the motor end-plates and appear as normal end-plates. After several months however the muscle fibers atrophy and become surrounded with connective tissue plugging the Schwann tubules and making downgrowth to the motor end plate difficult.

DANIEL RUGG, M.D.

Observations on Injuries of the Radial Nerve Due to Gunshot Wounds and Other Causes. S. SOKOLIK. *Lancet Austral N Zealand J Surg*, 1948 17: 253.

The author's article is concerned with lesions of the radial nerve and is based on the personal records of 63 patients who were treated in the 115th Australian General Hospital during the period from 1941 to 1945. An accurate follow-up extending over a period of 4 years was possible and the follow-up examinations of all patients with radial nerve injuries were made by the same observer.

A detailed description of each case is presented. Nerves known to be severed were repaired in cases in which this was possible. Immediate local conditions being favorable while partial or complete lesions in which the anatomical condition of the nerve was not known were given every opportunity to recover spontaneously before resorting to exploration. In general exploration was not contemplated within 6 months of the injury. It was the experience of this author as well as others that the majority of the nerve lesions recover spontaneously and show some signs of recovery within 6 months. In 45 patients the nerve recovered spontaneously without exploration.

In 2 patients a severed nerve was sutured immediately after the injury. In 15 patients nerves were explored and of these 2 were in the state of continuity not requiring repair, 5 were sutured, 2 were grafted and 6 were subjected to tendon transplantation owing to irreparable damage to the nerve.

The 2 nerves which had been grafted and 3 of the 5 which had been sutured did not recover and ultimately the patients required tendon transplantations.

The end results in the case of the 17 explored nerves were as follows: sutured with recovery 5 in continuity with recovery 3 and irreparably damaged 10. There was a high incidence of irreparable lesions due to gunshot wounds which resulted in a fracture of the humerus.

The relative merits of early and late exploration of clinically complete lesions is discussed. Evidence is presented which lends emphasis to the belief that the majority of injured nerves will recover spontaneously if treated conservatively, and that if early exploration is undertaken it is advisable to preserve the continuity of the nerve, regardless of the pathological changes present until it has been given an opportunity to recover spontaneously. While early exploration (by permitting prompt suture) is of value in cases of complete severance of the nerve it is urged strongly that nerves found in continuity should not be disturbed.

A delay of 6 months before suture is not necessarily prejudicial to the end result. The time element is only one of many variable factors affecting the restoration of function following suture and further investigation is required to evaluate correctly the influence of this factor.

Attention is directed to the dangers of too prolonged immobilization and the value of physiotherapy is stressed.

When axones have been interrupted significance is attached to the initial delay, which has been defined as the time between the injury and the entry of the regenerating axones into that portion of the nerve distal to the site of injury. (The time taken for the completion of those muscular changes upon which the restoration of voluntary contraction depends has also been included.)

A method for calculating this delay has been described.

a. The duration of the initial delay was a measure of the severity of the nerve lesion.

b. The initial delay was related to the time taken by the regenerating axones to reinnervate the entire motor field subsequent to the onset of recovery. In general long and short initial delays were associated with long and short periods of reinnervation.

c. An initial delay of up to 10 weeks followed the mildest cases of axonotomies, which were usually due to the simplest types of injury such as those associated with simple fractures of the humerus. More severe injuries, such as those due to gunshot wounds associated with fractures of the humerus, infection, and extensive scarring were followed by an initial delay of approximately 4 months. This was also the usual period of delay following suture. It is, however, difficult to differentiate between simple and severe nerve lesions, since the nature and severity of the causative injury was not a reliable guide.

The maximal period intervening between the injury and the onset of spontaneous recovery (latent

period) which proceeded to completion was 10 months. In the majority of nerves regenerating spontaneously however recovery had appeared by the end of 6 months.

The probable date of recovery (spontaneous or after suture) can be calculated from a knowledge of (1) the presumed initial delay (2) the level of the lesion, and (3) the rate of regeneration. Information relating to these three factors has been provided.

The approximate time when voluntary contraction may be expected in the last muscle to be reinnervated may be calculated by adding from 11 to 23 weeks, according to the type and severity of the nerve lesion, to the date of the onset of recovery in the first muscle to recover.

The regeneration of motor fibers was not always accompanied by a corresponding recovery of sensory function.

HOWARD H. LARSEN, M.D.

Experimental Contribution to the Problem of Reconstruction of Peripheral Nerves After Traumatic Lesions (Experimenteller Beitrag zum Problem der Wiederherstellung von traumatischen Läsionen peripherer Nerven) *MADEIRA J. VELOSO* *Revista de Medicina* 94, 15, 1938.

In a review of degenerative and regenerative processes in the nerves following trauma, the author describes the customary methods of treatment of nerve lesions. If an end-to-end union is impossible, autotransplantation must be taken into consideration. No cuffs are employed because they interfere with vascularization of the nerve endings.

In the author's experiments on rabbits the employment of woman's hair as a suture material proved very reliable because it has a sufficient tensile strength and produces hardly any reaction. The author advocates the use of stiff cuffs made of plexiglass and filled with autogenous plasma because they prevent formation of scar tissue which may interfere with the growth of axial cylinders, and because the autogenous plasma with its fibrin coagulum is a structure propitious to advance of the axial cylinder.

Contrary to the opinion of American writers, the author does not believe that the plasma clot is able to replace a nerve suture. The stiff cuff prevents a compression of the suture line by a callus or firm cicatricial tissue. Such compression may occur even if the nerve suture line is made in intact muscle.

In the author's experiments on 20 animals, necrosis of the nerve endings surrounded by a cuff did not take place in a single case. Capillary beds within the nerve provide sufficient circulation.

Discussion on the Surgical Treatment of Hypertension. ROBERT PLATT, D. W. C. NORTHFIELD, F. A. McABERY, A. M. BORD, and Others. *Proc. R. Soc. M. Lond.*, 94, 41, 1938.

In the present discussion PLATT states that sympathectomy for hypertension is formidable and on

physiological procedure that the results on the whole are disappointing and that the claims of surgeons must be accepted only after close and careful scrutiny but that in some cases which are quite unpredictable a significant, lasting and beneficial reduction in blood pressure is achieved.

The cause of human essential hypertension is still unknown and therefore a purely physiological attack cannot be designed as yet. The author favors renal origin as the cause of essential hypertension. The subsequent damage to the cardiovascular system (and most hypertensive patients eventually die of cardiac failure or cerebrovascular accidents) is serious and therefore there may be justification in using nonphysiological means to reduce the blood pressure if they can be shown to have no serious untoward consequences.

Subsequent discussion was with reference to the extent of the sympathectomy in order to obtain adequate denervation of the splanchnic area.

The importance of very careful analysis in all series of cases was pointed out, in view of the variability of blood pressure levels in patients with essential hypertension in addition to the fact that hypertension may not carry the increased immediate risk to life unless diastolic levels reach 115 to 120. Furthermore the known fact that women tolerate hypertension better than men (and a symptomless hypertension may persist for years without progression) also must be taken into account in an analysis of any series of operative cases.

This author believes that if only cases of malignant hypertension were included in a survey and if operation was successful in 10 to 20 per cent of patients, the results would be significant whereas one would be skeptical of claims of improvement even in 70 per cent of mild cases of labial hypertension.

In the author's series of 38 cases the majority of people over 50 years of age were rejected as well as those with poor renal function, advanced cardiac changes or serious cerebral complications. Operation has not been recommended in patients with diastolic levels of 110 or below. An effort has been made to assess the prognosis without operation before any recommendations have been made.

Three operative deaths were reported. The results were good in 4 cases and worthwhile in 8 cases; failure occurred in 9 cases. Other cases were too recent or they had not had a complete operative course.

In conclusion the author believes that sympathectomy might alter the prognosis of severe hypertension favorably in 25 to 50 per cent of the cases. The question as to the extent of the sympathectomy required has not been determined with certainty and further studies are being conducted in this regard.

NORTHFIELD reviewed 46 cases of severe hypertension at the London Hospital. All of these patients had undergone sympathectomy. The group was highly selected and operation was carried out only on patients in whom the medical prognosis was known to be bad. The majority of patients had

malignant hypertension or renal disease with severe hypertension. A careful preoperative medical survey was carried out in all cases and particular attention was paid to the fundi. Based upon this criterion 80 per cent showed evidence of malignant hypertension although it was believed that in view of the preoperative duration of the disease the malignant phase had more recently supervened upon the benign phase. Normal fundi were present in only 4 out of 46 cases.

The Adson (subdiaphragmatic) approach was employed in the first 10 patients of this series with 2 operative deaths. In the remaining 36 patients the Smithwick operation was carried out with 6 deaths.

A detailed analysis of these cases is then given with reference to the changes in the fundi, the presence of cerebral symptoms, headache, impaired renal function and the postoperative results with particular reference to these factors.

Twelve males with essential hypertension survived bilateral operation and in 8 the blood pressure was not appreciably altered although survival occurred for periods of over 2 years and 4 years. In 3 patients there was a slight to moderate lowering and in one patient the blood pressure had been at normal for 4 months. Seventeen females survived the operation. In 6 of these the blood pressure was unchanged in 5 there was slight to moderate lowering and in the remaining 6 marked improvement was observed.

In the group with renal hypertension the blood pressure improved in 3 cases and was unaltered in 4. Patients with headaches were greatly benefited. The optic fundi were usually dramatically improved following operation.

The operative procedure consists in removal of the sympathetic chain from the ninth dorsal to the second lumbar ganglion inclusive in addition to removal of the splanchnic nerve in the same area. A further description of operative technique and anesthesia is given.

The necessity of subjecting surgical methods to careful testing under controlled conditions is pointed out by D'ARREU who has adopted the following criteria: (1) retinal hemorrhages and exudates with retinal edema or papilledema, (2) a history of hypertensive encephalopathic incidents, (3) a fixed high diastolic pressure around 150. All cases were included on one or more of these grounds.

It is contended that operation should be performed in every case of the worst form of hypertension if severe kidney damage has not yet occurred. The operative technique employed is essentially of the Smithwick type with excision from the eighth thoracic to the first lumbar ganglion at least on each side and with excision of the celiac ganglion and the greater lesser and least splanchnic nerves as high as possible. Eight cases are reported in which marked improvement was observed in the fundi in all but one patient who was almost blind at the time of operation. This patient died 11 weeks after the second operation. A material drop in blood pressure was recorded in 5 of the 8 patients.

BOYD expressed the belief that the operative technique for complete denervation of the splanchnic area should include removal of the sympathetic ganglia as high as the third dorsal and to include the third lumbar ganglion below. The procedure is carried out with two incisions. The twelfth dorsal to the third lumbar ganglion are removed through an oblique muscle-cutting incision in line of the twelfth rib part of which is resected. The upper segment and thoracic splanchnics are removed transpleurally access being gained by resection of the eighth rib. Subsequent studies to determine the completeness of the operation have been carried out by mapping cutaneous areas of anhidrosis by means of an extremely sensitive electrodermatometer designed by A. H. Ratcliffe.

WRIGHT suggested that the choice of operation is very difficult to make but a useful clinical experiment would be to reoperate on some of the Adson and Peet operative failures, remove the ganglionic chain trans thoracically, and endeavor to obtain further facts and it is quite possible that cervical sympathectomy obtained by the trans thoracic operation might lessen the risk of cerebral and ocular hemorrhage.

WILSON pointed out that there are many instances in which the blood pressure level does not fall appreciably following operation, but that the hypertension changes in quality even though quantitatively it is unaltered. The malignant character of the disease which leads to retinal changes, increased intracranial pressure, renal vascular lesion and left ventricular failure may be modified so that the hypertension becomes relatively benign. Unfortunately this alleviation may not be of long duration although in women the results are much more impressive.

ORRIDGE made a point with regard to the severe drop in blood pressure during the operative procedure. He believes that this is due to a increased pressure gradient to the brachial artery due to spasm of arteries proximal to the flow rather than to a fall in the head of pressure at the center. Intravenous injection of 200 mgm. of procaine will

relax vascular spasm and produce a rise in brachial blood pressure in 2 or 3 minutes. This rise could not be reproduced in a healthy patient under anesthesia, the injection resulting only in a slight tachycardia but without rise in pressure.

HOWARD A. BROWN, M.D.

Effects of Novocainization of the Contralateral Stellate Ganglion on Pain in the Limbs and Amputation Stumps (Les effets de la novocainisation stellaire contralatérale sur les douleurs des membres et des moignons) A. JUNG, Rev. k: Par 948 67 72

After paying tribute to Leriche the author discusses the effects of injecting novocain into the stellate ganglion in cases of pain in the extremities. Injection into the ipsilateral ganglion interferes with the peripheral mechanism of pain but contralateral injection affects the central path also. In this way it may be possible to dissociate the peripheral pain from the central element of pain. Injection on the contralateral side produces vasodilatation in the region in which the pain is registered in the brain there is a sympathetic block to the pain registering zone. Unilateral stellate block in Raynaud's disease affecting both hands is said to produce some contralateral effects as measured by temperature studies, although the classical Horner's syndrome is not produced.

Against this background of spread of similar effects to the contralateral side the author contrasts dissimilar effects on a limb in which one stellate ganglion or the other is injected with novocain. Nine amputees were injected. Ipsilateral injection caused the phantom limb to feel longer whereas contralateral injection caused it to feel shorter. Three other cases in which the upper limbs were bilaterally amputated produced the same picture elongation on the ipsilateral, and shortening on the contralateral side from the operation. Five other cases of phantom limb are mentioned in which benefit was obtained from contralateral stellate ganglion injection.

There are two references to the French literature.

ADRIEN VER BRUGHEM, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Is Chronic Cystic Mastitis a Precancerous Lesion?
Ten Year Follow Up Study of 26 Cases. H. LINTNER REED *Arch. Surg.* 1948, 56 338

Three types of chronic cystic mastitis can be distinguished histologically (1) simple chronic cystic mastitis (2) chronic cystic mastitis with papillary proliferation and (3) chronic cystic mastitis with atypia.

There is no unanimity of opinion concerning the nature of chronic cystic mastitis its relation to cancer or the best method of treatment. The treatment of the condition should be governed by the histologic type of the lesion. Simple chronic cystic mastitis which is present in more than 80 per cent of cases is treated by local excision of the involved area only and regular follow-up examinations of the patients are regarded as unnecessary. Chronic cystic mastitis with papillary proliferation (4 per cent) is also treated by local removal but the patients are advised to report for clinical examination every 6 months after the operation. Chronic cystic mastitis with atypia (15 per cent) is treated by simple mastectomy with regular postoperative follow up examinations.

Twenty-six patients with chronic cystic mastitis of various types were treated according to these principles and were followed for from 10 to 17 years after operation. Cancer of the breast did not develop in a single instance.

SAMUEL KAHN M D

TRACHEA LUNGS, AND PLEURA

Carcinoma of the Trachea. CLARENCE W ENGLER.
Ann. Otol. Rhinol., 1948, 57 419

Any instance of carcinoma of the trachea is worthy of report, in view of the rarity of the condition. The number of cases of primary carcinoma of the trachea hitherto reported is approximately 300. In practically all of the cases reported in the last decade a careful histologic study of the tumors was made yet much confusion remains concerning their exact classification.

The type of lesion about which most confusion exists is that variously designated as cylindroma basal cell carcinoma, mixed tumor of salivary type cylindric epithelioma, and adenoma. If these tumors are not of the same type the reported descriptions of them contain striking similarities and it seems to be difficult to recognize any criteria for distinguishing one from the other. It appears that this group of neoplasms although essentially benign may undergo malignant change and must be considered as potentially if not actually malignant. Some distinction, however should be made between this type of questionable or low grade malignancy and the more rapidly developing types. This distinction is essential in evaluating the probable results of treatment.

Since any tumor that grows large enough to obstruct the tracheal airway is incompatible with life early bronchoscopy and radical removal of any tracheal tumor in patients whose symptoms suggest tracheal obstruction is essential. If this were done, cancer of the trachea could be prevented in some cases at least and the results of treatment of frankly malignant tumors would be improved. This belief is strengthened by the fact that, in the majority of cases of carcinoma of the trachea the metastases are only regional.

Two cases are reported one a definite primary carcinoma of the trachea the other so far advanced when first observed that it could not be determined even at autopsy whether the lesion was primary in the trachea or in the esophagus.

SAMUEL KAHN M D

ESOPHAGUS AND MEDIASTINUM

Resection of the Thoracic Esophagus for Carcinoma Located Above the Arch of the Aorta; Cervical Esophagogastrostomy JOHN H. GARLOCK. *Surgery* 1948 24 1

The least frequent site for carcinomatous involvement of the esophagus is between the border of the aortic arch and the apex of the chest. In this region the esophagus is in close proximity to the trachea, the great vessels and the vagus and recurrent laryngeal nerves. Local involvement of these adjacent structures frequently results in inoperability. The author describes a procedure used to excise a large tumor in this area with esophagogastric anastomosis. He mentions that stimulation of the vagus nerves may set up the vagovagal reflex which may result in irreversible disturbances of cardiac function. He further suggests that atropine preoperatively may prevent or alleviate this result.

The case report is that of a 46 year old female patient admitted to the Mount Sinai Hospital New York on December 24 1946. The duration of her symptoms was 3 months beginning with dysphagia on swallowing solid food. At the time of admission she could swallow only liquids. There had been a weight loss of 15 pounds. Roentgen ray examination revealed a large irregular mass partially obstructing the esophagus at the upper level of the aortic arch. On esophagoscopy a large irregular grayish tumor was seen and biopsy revealed an infiltrating hornifying squamous cell carcinoma. On January 3 1947 operation was performed. The neck was explored through an oblique incision along the left sterno-mastoid muscle. It was decided that the tumor was resectable and the wound was closed temporarily. The left seventh rib was removed the mediastinal pleura opened and a large tumor of the esophagus was found extending from the middle of the arch to 1 inch above the arch of the aorta. It was dissected

free. Through an incision in the diaphragm the cardiac end of the stomach was freed and the whole stomach was mobilized by dividing and ligating the vasa brevia, the left gastrophrenic vessels and left gastric artery. The gastrosplenic ligament was left attached to the stomach. The esophagus was divided at the cardiac junction and brought up to a supra-aortic position. The esophagus was brought through the reopened neck wound, the esophageal branches of the inferior thyroid artery being preserved. The mobilized stomach was pushed through the apex of the chest and out of the neck without any tension. Multiple silk sutures were placed between stomach and both edges of the mediastinal pleura. The diaphragm and chest were closed and under water drainage was started.

Returning to the cervical wound the esophagus was divided and a two-layer interrupted silk suture anastomosis with the stomach was done. At no time during the procedure was the patient in shock. Later in the morning there was marked cyanosis and respiratory distress, and the patient died very quickly. Complete postmortem did not reveal any cause of death. The author believes the patient's death was caused by physiologic disturbances possibly caused by vagal stimulation. In this case the stomach was mobilized above the apex of the chest without impairment of its vitality. The esophageal branches of the inferior thyroid artery were preserved for blood supply to the esophageal stump.

It is suggested that this procedure may be used for extensive impermeable lye strictures of the thoracic esophagus. ROBERT E. FLOREN, M.D.

Subtotal Esophagectomy and Esophagogastronomy for Illing Intrathoracic Esophageal Lesions. MILTON E. DELLAKY and ALTON OCHSNER. *Surgery* 94:3 3 935

This report is concerned with the author's experiences with the operation of Garlock and of Sweet as applied to lesions of the upper portions of the intrathoracic esophagus. Two cases are reviewed in detail with emphasis on the technical considerations of the operation.

Perhaps the most difficult feature of the operation is the performance of esophagogastric anastomosis at a high level in the chest. If the incision in the thoracic wall is made sufficiently high to facilitate the procedure difficulty will be encountered in mobilizing the stomach adequately, whereas if the incision is made low enough in the chest to facilitate the latter procedure the anastomosis becomes difficult. To solve this problem Garlock opened the chest through the sixth or seventh interspace and then divided the fourth to the eighth or fifth to the ninth ribs posteriorly to form a T-shaped incision in the thoracic wall. Sweet achieved his purpose by entering the chest through the bed of the eighth rib and then divided the seventh, sixth, fifth and fourth ribs paravertebrally.

The authors have altered these approaches somewhat. In their first case the chest was entered through

the bed of the left seventh rib and the sixth and fifth ribs were divided paravertebrally. In the second case the chest was entered through the bed of the left sixth rib, and the fifth rib was divided paravertebrally. Neither of these approaches proved completely satisfactory, for in order to provide adequate exposure for mobilization of the stomach in both it was found desirable to extend the incision across the costal arch anteriorly into the abdomen. This provided an excellent exposure of the lower segment of the esophagus and of the stomach. Although it was well tolerated in both cases, it obviously increased the time and magnitude of the operation.

Ideally the incision should permit adequate exposure low in the chest in order to facilitate mobilization of the stomach and high in the chest to provide ready access for the esophagogastric anastomosis with a minimum of operative trauma. The authors therefore suggest that it may be better to make an incision in the left thoracic wall which begins paravertebrally over the fourth rib, extends caudad to the seventh rib and then curves anteriorly to follow the seventh rib to its costochondral junction. The pleural cavity could then be entered through the bed of the subperiosteally resected seventh or eighth ribs. After it has been determined that the lesion is resectable especially in malignant cases, and the esophagus is freed from its bed, the stomach can be mobilized through the diaphragm, brought up into the chest and the diaphragm closed around it. The remainder of the operation, that is, the esophagogastric anastomosis can then be done through a higher level by mobilization of the upper flap of the incision in the thoracic wall and entrance into the pleural cavity through the bed of the subperiosteally resected fourth rib. In this way only one incision is made in the soft parts of the thoracic wall with provision for two levels of exposure.

The details of the operation as performed are outlined. The esophagus is freed by careful blunt and sharp dissection from its bed in the mediastinum. The esophageal vessels from the aorta and bronchial arteries are ligated and divided. The esophagus above the aortic arch is exposed through an opening in the mediastinal pleura behind the left subclavian artery. This permits dissection of the esophagus behind the aortic arch to be carried out from above and below. Once the esophagus has been completely freed from its bed the phrenic nerve is crushed, and mobilization of the stomach is begun through a radial incision in the diaphragm from the hilus to its costal attachment. The stomach is mobilized by section of the gastrosplenic, gastrosplenic, and gastrophrenic ligaments and the vessels contained in them are being taken to preserve the vascular arches along the greater and lesser curvatures. The left gastric artery is severed close to its origin, rather than by multiple division of its branches. The esophagus is then separated from the stomach between clamps and the gastric stoma closed by inverted suture. The esophagus is brought out from under the aortic arch to the left and above the aorta behind the left subclavian ar

tery The anastomosis is then performed after the stomach is brought up into the chest. It is preferable to bevel the esophageal opening to allow a larger stoma. After the completion of the esophagogastric anastomosis the stomach is attached to the parietal pleura posteriorly with interrupted sutures. The opening in the diaphragm is then closed first by attachment of its edges around the stomach just above the pylorus and then by approximation of the remaining edges. Oxygen is administered during the first 24 hours, and fluids and blood are administered as required. The patient is allowed to drink fluids early. He can usually take a soft diet by the third day and a full diet by the fifth postoperative day. Early ambulation is desirable. HAROLD LAUFMAN, M.D.

MISCELLANEOUS

Pulmonary Valvulotomy for Congenital Pulmonary Stenosis. R. C. Brock. *Brit. M. J.* 1948, 1: 1131

Although cardiac surgery may be said to have begun in 1896 when Rehn successfully sutured a wound of the heart, and has advanced greatly through the intervening years by the work of such people as Gross and Hubbard (patent ductus arteriosus procedure, 1939) Crafoord and Nylin (aortic coarctation resection 1945) and Blalock and Tausig (surgery for pulmonary valvular stenosis 1945) the author points out that comparatively little has been accomplished in directly attacking the structures of the heart. Several attempts have been made in past years to dilate stenosed valves both by mechanical means and by digital manipulation but present surgical thinking in general considers this approach impractical.

The author emphasizes the need for completely investigating the possibilities of direct approach to the heart structures as opposed to the present widely used indirect procedures which bypass stenosed valves. The Blalock method is criticized because the fistulous communication may not grow as the child does and because of the potential danger of the artificially created ductus arteriosus.

Since the best way to assess the state of the cardiac valves is direct examination, a suitable cardioscope is of prime importance. Such an instrument was devised by Allen and Graham (1922). This instrument is inserted into the heart, the blood is displaced and the valves can be inspected directly. Although the pulmonary valve can be approached either through the left pulmonary artery or the left ventricle, the author considers the ventricular route better.

Direct external examination of the heart will help to confirm the diagnosis of pulmonary valvular stenosis. There is a thrill in the stem of the pulmonary artery immediately distal to the valvular stenosis. Often the artery in this site is dilated and forms a thin walled aneurysmal bulge. When a subvalvular stenosis is present, no such localized and characteristic thrill is felt. Rather, the thrill is coarse and is felt below the level of the valves and is present over a greater area.

Three patients presenting the tetralogy of Fallot, aged 11, 18 and 23 years respectively were submitted to operation with a direct valvular approach. In each the valves were first dilated with a valvulotome which was passed through the left ventricle. This divided the stenosed valve. Next a dilating forceps was passed through the valvular lumen and the valve enlarged. Following surgery these patients exhibited marked improvement with regard to their symptoms. Two of the patients however developed vascular complications, one an arterial embolus to the leg and the other a hemiplegia. The fact that these results have been noted after the Blalock procedure is mentioned.

The author concludes that pulmonary valvulotomy is a feasible technique. He does not contend that it should supplant the Blalock method of treating pulmonary stenosis, but rather suggests that the direct approach to cardiac lesions should be more fully investigated. C. FREDERICK KITTLE, M.D.

Aortic Pulmonary Anastomosis. WILLIS J. POTTS and STANLEY GIBSON. *J. Am. M. Ass.* 1948 137 343.

Forty five operations are reported in which the aorta and pulmonary artery were anastomosed for surgical relief of congenital pulmonary stenosis according to the method devised by Potts, Smith, and Gibson in 1946. Seven additional patients underwent exploratory thoracotomy without anastomosis.

The tetralogy of Fallot is by far the most common condition with inadequate pulmonary circulation. This syndrome consists of pulmonary stenosis, inter-ventricular septal defect, overriding of the septal defect by the aorta, and hypertrophy of the right ventricle. Characteristically there is marked cyanosis and clubbing of the fingers and toes. There may be retarded mental development and malnutrition. Physical examination discloses a normal sized or slightly enlarged heart with a systolic murmur audible along the left sternal margin in the second and third left interspaces, sometimes accompanied by a thrill. Roentgenologic study reveals a boot shaped heart and fluoroscopic inspection discloses the absence of pulsations in the hilar regions. In the left anterior oblique position the pulmonary window is unusually clear. The electrocardiogram shows a pronounced right axis deviation. There are varying degrees of polycythemia and diminished arterial oxygen saturation. No apparent correlation exists between the degree of cyanosis, polycythemia, and the patient's limitation of activity.

Once the diagnosis of Fallot's tetralogy is established it is necessary to determine the position of the aortic arch before operation is undertaken. In from 15 to 30 per cent of the cases the arch descends on the right. To perform anastomosis the chest should be entered on the side where the arch lies. This location can usually be determined by inspection of the chest roentgenogram. If not, use of a barium swallow with observation of the aortic indentation on the esophagus will be decisive.

Tricuspid atresia must be differentiated from the tetralogy of Fallot. The physical signs and clinical symptomatology are essentially the same but two important differences distinguish tricuspid atresia: the roentgen silhouette reveals enlargement of the left ventricle and absence of the normal fullness of the right ventricle, and left axis deviation is revealed by the electrocardiogram. Four patients exhibited this syndrome and in 3 an aortopulmonary-artery anastomosis was done with striking improvement in their cardiac status. In the fourth patient no anastomosis could be done because of a rudimentary pulmonary artery.

Skillfully given intratracheal anesthesia is imperative because the narrow margin of safety in these severe grades of anoxemia and the emergencies which arise during cardiac and thoracic surgery demand thorough knowledge and resourcefulness. The child is placed in a lateral position and the incision is made on the side where the aortic arch lies. No sponges are used within the chest but blood is lavaged away with a stream of isotonic saline solution. Considerable variation in size of the pulmonary artery is found, the average artery being from 5 to 8 mm. in diameter. The left pulmonary artery is usually longer than the right and does not break into branches before entering the hilus as does its counterpart. The left pulmonary artery lies fairly near to the aorta and courses in almost the same plane as the aorta whereas the right pulmonary artery lies along the inferior portion of the hilus of the lung and pursues a route almost perpendicular to the aorta. Although some uncertainty was felt about anastomosing the pulmonary artery to an aorta lying at right angles such fears have been unjustified by the uneventful course of 7 patients in whom this was done.

The anastomosis is performed after temporary obliteration of the pulmonary artery by placing a doubled ligature about it. One end of each suture is threaded through the flange on a Potts aortic clamp

so as to insure good approximation of the pulmonary artery to the aorta. The site of the anastomosis is determined by the position of the pulmonary artery although it is usually about 3 cm. distal to the origin of the subclavian. A stoma is made in the aorta and the pulmonary artery and the anastomosis is sutured with over and over continuous 5-0 silk.

Postoperatively an oxygen tent may be needed and penicillin is given routinely. Complications have been few. Severe tracheobronchitis with laryngeal edema occurred in 3 children. Three had a mild tracheobronchitis satisfactorily relieved by steam. In 4 aspirations of fluid, air or both were necessary. Cerebral anoxia in one patient caused total paralysis for 3 days, but recovery was complete. The average length of hospitalization following the operation was 14 days.

Four patients died a mortality of 8.8 per cent. The deaths were due to cerebral thrombosis in 2, postoperative shock and tension pneumothorax (secondary to apical tuberculosis) in 1 and hypothalamic hemorrhage in 1. Seven operations were exploratory because of small pulmonary arteries which made an anastomosis infeasible or because of an Eisenmenger complex. Three of the 7 patients failed to survive thoractomy.

Of the 41 patients who survived operation, 39 showed great improvement in their condition, being relieved of cyanosis, having gained weight, and being able to live fairly normal lives. Two patients are better but still exhibit slight cyanosis. The anastomotic channels are open in all, this being ascertained by the presence of a faint soft systolic and diastolic humming murmur. No child was refused surgical treatment if the preoperative diagnosis indicated a pulmonary circulation which might be improved by this procedure. It is appreciated that these children do not have a normal cardiac mechanism and that extra work is added by creation of the artificial ductus arteriosus. C. FREDERICK KITTLE, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Mesenteric Vascular Occlusion J D RIVES, L. H. STRUGG and I. M. ESKRIG. *Ann Surg* 1948 127 887

Infarction of the mesenteric vessels which is not associated with the thrombosis incident to local infection or trauma, as in appendicitis peritonitis or operative injury is a very uncommon disease and is usually associated with advanced cardiovascular disease. The mortality is extremely high either because of the state of extremis already present in a patient suffering from severe arrhythmias or congestive heart failure with mural thrombus formation or because the diagnosis and treatment has been too long delayed in other forms of the disease which are not associated with cardiovascular sources. Death from the first cause may be unavoidable but from the second it frequently is not.

Mesenteric vascular occlusion in the beginning may be either arterial or venous in type but thrombosis in one type of vessel is generally followed by involvement of the other so that at a later pathologic examination it is generally impossible to determine in which vessel the process began. The pathophysiologic changes are the same in arterial venous or combined types of occlusion and, depending on the degree of ischemia present and the development of collateral circulation these consist of (1) no changes (2) paralytic ileus with no tissue alteration other than congestion (3) mucosal ulceration (4) ecchymoses into the bowel wall (5) focal or massive hemorrhagic infarction and ultimately (6) perforation. Gas does not tend to accumulate in the involved segment, presumably because the infiltrated bowel wall is incapable of distention. At laparotomy the infarcted loop is found lying deep in the abdomen weighted down by its fluid contents.

Arterial mesenteric vascular occlusion is caused by emboli originating in the heart, aorta, or pulmonary veins (mural thrombi atheromatous plaques) by thrombus formation due to disease of the vessel walls; secondarily to infarction of the bowel due to venous occlusion and probably due to other causes. Venous occlusion however is almost always due to thrombosis as the result of (1) slowing of the venous flow (2) diseases of the veins or perhaps (3) alterations in the clotting mechanism. Portal hypertension cavernomas of the portal system and congestive heart failure are the most common demonstrable causes. In the authors cases arterial occlusion was more common (6 to 4) than the venous type.

Whatever the type or cause of the mesenteric blockage there are but two clinical pictures. The first is due to a sudden obstruction of a major mesenteric vessel with attendant infarction the second is one of increasing ischemia which may either subside or progress to the state of complete infarction but the

picture is identical no matter how the occlusion developed. Sudden obstruction of a major vessel in the mesentery is almost always due to advanced cardiovascular disease typically the patients already suffering from a severe ailment of the heart dramatically exhibit abdominal catastrophe manifested by acute pain nausea, vomiting and profound shock. In occlusions that develop more slowly there are three clinical stages (1) a period characterized by hyperperistalsis with colicky pain and nausea (2) an interim of intestinal paresis that produces the syndrome of partial intestinal obstruction and (3) a phase of total intestinal strangulation.

The treatment is extensive surgical extirpation of all the involved intestine numerous resections of massive amounts of bowel with a successful outcome have been reported. Theoretically anticoagulants should be of great value in prophylaxis and post operative treatment, but their use is not recommended for definitive therapy.

Features that aid in the diagnosis are (1) a history of a known predisposing cause (2) the character of the onset (3) the early disappearance of peristalsis in a case of suspected intestinal obstruction (4) the occurrence of leucocytosis in such a case without evidence of peritonitis and (5) the development of shock when all other evidence points toward partial obstruction.

WAYNE FIELD CAMERON M D

Lymphangioma of the Mesentery G V BRINDLEY and G V BRINDLEY JR. *Ann Surg* 1948 127 907

Although benign neoplasms of the mesentery are unusual and lymphangiomas are particularly rare these lesions are to be considered in the differential diagnosis of intra-abdominal tumors. Some 500 cases of chylous cysts of the mesentery were reported in the literature up to 1939.

The diagnosis is largely made only at the time of autopsy or celiotomy. Excision is the treatment of choice although resection of a portion of the adjacent bowel may be required. Marsupialization may be done when excision is not feasible.

The authors present a case report of a large lymphangioma of the mesentery of the jejunum which was successfully excised.

WAYNE FIELD CAMERON M D

An Occult Richter Hernia; Its Particular Symptomatology and Results (Ernia di Richter occulta, sua particolare anatomologia ed esito). GIULIO TOCCI. *Pol clinico sez. chir.*, 1948, 55 68.

The author's 60-year-old male patient had always been inclined toward constipation. For the past 2 years he had been getting thinner and thinner. Five years ago there was an attack of abdominal pain and vomiting which had corrected itself without special treatment. About 6 days previous to his entry into the hospital he had taken a saline laxative and with

the purgative effect experienced pain in the right lower quadrant of the abdomen. This pain persisted following the purgation despite a strict liquid diet. No further fecal emission was made and for 3 days no gas or only very little was passed and the abdomen became distended. The patient had begun to vomit. About all that the physical examination uncovered, aside from the general toxic debilitated state was the distended abdomen with a certain amount of visible peristaltic unrest. However the roentgen examination disclosed the narrowing of the intestinal lumen at the terminal end of the ileum.

At operation this narrowing was found to be the result of the intrusion of a portion of the circumference of the small bowel, about 20 cm from the ileocecal valve into a small depression leading into the internal aperture of the inguinal canal. The incarcerated portion of the bowel wall was easily removed from the inguinal indentation—it was only about 1.5 centimeters deep—and seemed intact. The small diverticular dilatation was situated opposite the mesenteric attachment. It flushed after being loosened with what appeared to be a normal blood supply, so that retention was not considered nor was any effort made to exclude the loop from the general abdominal cavity. The first postoperative day and night passed uneventfully however the following evening the toxic picture of generalized peritonitis appeared and the patient died the following morning. Autopsy revealed from 2 to 3 cm of the terminal ileum in a necrotic condition however there was no actual perforation. The arteries in this section of the intestinal loop were markedly dilated with a bloody suffusion involving all of the layers of the intestinal wall. Practically all of the venous channels, the local channels and those leading up into the mesentery were thrombotic.

In reporting this case the author wishes to emphasize three aspects—the probably etiological participation of the purgative in the initiation of the process of herniation, the possible influence of the loss in body weight and the increased mobility of the abdominal contents in general, and the need for extreme care in judging the viability of the incarcerated intestinal wall. JOHN W. BROWN, M.D.

Whole Skin-Graft Repair of Inguinal Hernia. C. M. MARSDEN. *Brit J Surg* 9:43 33 390.

The present report deals with 63 inguinal hernias which were repaired by skin grafts, and a follow-up of 136 of the patients at 12 months. The types of hernia were classified as oblique, 70 direct, 77 and saddlebag, 7. Of these hernias, 86 were recurrent with an average duration of 6 years, and 77 were simple with an average duration of about 3 years. A postoperative febrile reaction was noted in 75 per cent of the patients. The buried skin graft is infected material, but the tissues appear to be able to overcome this, in doing so there is a general reaction with fever. There were 10 infections, all trivial, and 5 cases of persistent sinus. Unabsorbable suture material was used.

At 6 months there were 5 per cent and at 12 months 0.8 per cent of recurrences in the group followed. There was a high percentage of recurrences when the sac of a direct hernia was not excised. The author states that the recurrence rate though high, is not excessive considering the type of hernia repaired. JOHN L. LINDQUIST, M.D.

Operative Technique for Umbilical Hernia Utilizing Skin Grafts (Técnica operatoria para hernia umbilical utilizando injerto de piel). JOSE V. URBANO and ROBERTO A. GARCIA. *Presse méd. argnt.* 9:43 35 717.

Umbilical hernia has a great propensity for recurrence especially in the aged and obese patient. Some authors give the recurrence rate as high as 30 per cent.

In order to obtain a solid anterior abdominal wall to prevent recurrences it has been sought to place as many layers as possible to re-enforce the weakened zone occupied by the umbilical ring. Since with the passage of time the aponeurotic planes may give way there has been employed in front of the hernial ring, in addition to the fascial repair a full-thickness skin graft.

The technique of repair is a modification of that proposed by Rafael Araya in 1926. General measures include preoperative bed rest, reducing diets for obese patients, medical treatment for any coexistent organic deficiencies and in the event of very large hernias progressive pneumoperitoneum as suggested by Goffi Moreno.

For a few days prior to operation the operative site is carefully cleansed with soap and water and therapy is instituted to any local intertrigo or eczema. For the 3 days immediately preceding operation the umbilicus and the surrounding area is painted with iodine and alcohol and covered with a sterile dressing. And finally a few hours before surgical intervention penicillin is given in a dose of from 300,000 to 500,000 units.

When the abdominal wall is flaccid, local anesthesia is the anesthetic of choice; however, if the abdominal wall is tense a general or spinal anesthetic is preferable.

If the skin which covers the hernia is acceptable that is to say it has the characteristics of normal skin and is not debilitated or thinned or fissured or excruciated it may be employed as the graft. However if these conditions are not fulfilled and a lipectomy is anticipated, the skin graft may be obtained from one end or the other of the elliptical area excised. Or if an operation is contemplated in which the skin covering the umbilicus is to be conserved, the skin graft may be taken from another area.

If the case requires lipectomy in addition to repair of the umbilical hernia, an elliptical incision is made about the umbilicus at right angles to the long axis of the body. The extent of the lipectomy planned will govern the size of the incision. The full thickness graft is excised from one end or the other of the ellipse. The amount of skin is removed

from the portion excised and this is placed in moist gauze or physiological saline solution. The latter procedure is preferable since any cellular or fatty tissue left in contact with the graft will imbibe liquid and be more easily removed later.

After the subcutaneous dissection of the ellipse is completed and the aponeurosis is reached the dissection is carried to the neck of the hernia. The opening of the sac, and the removal and treatment of the hernial contents differ in no way from the classical technique.

The upper and lower lips of the incision are then freed from the anterior rectus sheath. The separation of the free edges of the incision may be maintained by Gelpi self-retaining retractors.

Once the peritoneum is closed the edges of the aponeurotic onifice are approximated and sutured. If it is not possible to separate the peritoneum from the fascia, both are closed in a single plane.

Curvilinear semi-elliptical flaps are then cut in the anterior leaves of the rectus sheaths with care not to carry the incisions medially beyond the linea alba. The free edges of these flaps are then approximated medially and fixed together with interrupted sutures. Following this the muscle subjacent to the fascial layers just rearranged is freed from the posterior leaf of the rectus sheath. If the rectus muscles do not come together easily in the midline the incision in the rectus sheath may be extended vertically 1 cm. at each end. Here again great care must be exercised not to impair the integrity of the single layered aponeurotic plane medial to the linea alba.

The skin graft is then carefully inspected and any lobules of adipose or connective tissue are removed from the raw surface. The tissue is then cut approximately in the shape of an ellipse. After it is cut, the graft may seem too small. However the graft has elasticity and will stretch when sutured in place.

The graft is placed raw surface downward on the base formed by the rectus muscles, over the central portion of the hernial repair with the major axis oriented vertically. It is then sutured at either extremity with care to pull the tissue taut during fixation. The lateral portions of the graft are introduced under the anterior leaf of the rectus sheath and sutured so that tension is applied laterally. After this sutures are placed at intervals of from 5 to 7 cm. around the perimeter of the graft. Upon completion the graft should have the tension of a tambour. The free lateral edges of the rectus sheaths should then be brought together as near as possible in the midline and sutured wherever they approximate each other.

The subcutaneous tissues and skin are then brought together with care to eliminate any dead spaces. The skin is then sutured. If desired two small rubber-dam drains may be used one at either end of the incision. Neither one should be in contact with the cutaneous surface of the graft. A pressure dressing is then applied.

With a skin graft of this sort there is always danger of infection therefore as a prophylactic measure

penicillin is given for the first 48 to 72 postoperative hours.

In the event that suppuration occurs the graft endures it and is not eliminated. Actually it functions as a foreign body and maintains the suppuration thus adding to the amount of granulation tissue formed and further strengthening the anterior abdominal wall.

The patient should remain in bed for a minimum period of 2 weeks preferably 3 and if the hernia has been very large for 4 weeks.

HAROLD W. BIRCHOFF, M.D.

GASTROINTESTINAL TRACT

A Contribution Toward Recognizing Acute Spontaneous Dilatation of the Stomach (Contributo alla conoscenza della dilatazione acuta spontanea dello stomaco) PAOLO COLOMBO *Arch. ital. mal. app. diger.*, 1948, 14, 98.

The author describes and comments upon a fatal case of acute gastroduodenal dilatation which came on during the sixtieth day of an illness caused by typhoid fever.

The etiology is not clear but the syndrome is made up of a compensated phase characterized by a gastroduodenal phenomenon and an uncompensated phase manifested by cardiocirculatory decompensation.

Reversible cases with recovery are those which do not go beyond the first phase either because of prompt therapeutic intervention or because of the spontaneous action of natural mechanisms of defense (adrenaline, prostigmine, cortin?).

The occurrence of this condition is considered rare and was found in 0.9 cases per thousand of typhoid fever hospitalized during a 20 year period.

Diagnosis is not always as easy as it was in the author's case in which in spite of prompt and intensive treatment by aspiration with the Foucher sound and parenteral therapy, the patient died within 9 hours of the onset of symptoms. The presence of fever, vomiting and signs of peritoneal irritation may lead one to believe that he is dealing with a partial or walled-off perforation. Operative intervention is fatal in these cases. Le Noir and Agasse Lafont report the death of the 8 patients operated upon or a mortality of 100 per cent.

LUCIAN J. FRODOU, M.D.

A Study of Gastric Mucosa in Various Diseases Affecting the Upper Part of the Gastrointestinal Tract WARD CARL MEYERS *Gastroenterology* 1948 10 923.

The material used for this pathologic study consisted of blocks taken from the gastric mucosa in 135 cases. A routine of microscopic examination was carried out and the following organization of data was considered: the thickness of the muscularis mucosae and external muscular coat, the number and characteristics of glands, the type of cell, characteristics of the stroma, type of muscularis mucosae and the degree of gastritis.

Thickness of the mucosa appeared to be of little comparative importance, except in the case of long standing pernicious anemia, in which the mucous membrane especially in the fundus was thinned. Thickness of the external muscular coat was of little consequence except in the case of long standing pernicious anemia, in which all the elements of the gastric wall undergo atrophy and destruction.

The length of the glands in cases of gastric and duodenal ulcer and in gastric carcinoma, with or without acid differed little. Shorter glands were found in cases of pernicious anemia in which gastric resection had been performed and they were still shorter if present at all, in cases of pernicious anemia in which necropsy was carried out. Comparative counts

of the number of fundic glands indicated that less destruction of epithelial elements had occurred in duodenal ulcer and that variable destruction occurred in gastric ulcer. In cases of gastric cancer with or without acid destruction was fairly uniform and slightly more severe. In all cases of pernicious anemia, severe to complete destruction of epithelial elements was noted. Tortuosity of the fundic glands, seen in severe gastritis probably represents an attempt on the part of remaining glands to compensate for the loss of destroyed epithelial elements by uneven regeneration and hyperplasia.

Except in cases of severe overwhelming atrophic gastritis, evidence of attempts at regeneration usually can be found in glandular elements. The finding of pinching off of glands by the muscularis mucosae was utilized in typing the changes in the muscularis mucosae presented herein. The formation of cysts presents evidence of severe destructive gastritis after erosion of surface epithelium with subsequent healing, leaving a blind gland buried in the mucosa.

Replacement of the cells of the gastric mucous membrane, including the chief cells by mucous goblet cells was present in all conditions except duodenal ulcer and was a minor finding in the fundus in cases of carcinoma with acid. Since replacement in the fundus was found in gastric ulcer and not in duodenal ulcer there is a possibility that the mucous membrane has greater resistance to extragastric ulcers. Also the presence of a minor degree of replacement in the fundi in cases of carcinoma with acid while the degree was major in the fundi in cases of carcinoma without acid, indicates a protective influence exercised by the presence of acid. In pernicious anemia, replacement was fairly complete. Grading of the degree of mucous replacement resulted in no conclusive findings. Paneth cells were found in 70.8 per cent of sections in which replacement was observed a slightly higher occurrence than that previously reported in the literature. On comparison it was found that the number of parietal cells was high in duodenal ulcers and diminished progressively through the other groups until in the cases of pernicious anemia in which necropsy specimens were examined no parietal cells were found.

Lymphocytic infiltration was far greater in the antrum than in the fundus in the cases of duodenal

ulcer and was definitely greater in the pylorus than in the fundus in the cases of gastric ulcer. In the carcinoma groups slightly higher grades of infiltration were found in the pylorus. No differences were observed in the groups with pernicious anemia. Edema of the submucosa is a common finding in all grades of gastritis. Hemorrhage into the submucosa was of no value in this comparative study because of the possibility that it was due to surgical manipulation. The incidence of fibrosis of the submucosa was higher in the more severe atrophic gastritis, lower in the less severe hypertrophic types. Fatty infiltration of the submucosa appeared to be definitely less in gastric ulcer and in pernicious anemia (necropsy specimens). Cellular infiltration of the submucosa was not extensive in ulcers, either gastric or duodenal, and was more extensive in cases of carcinoma and pernicious anemia in which surgical specimens were examined. Cellular infiltration in atrophic gastritis, in cases of pernicious anemia in which the necropsy specimens was examined, was definitely milder.

The state of the muscularis mucosae offers one of the most salient points in the estimation of the chronicity of gastritis. The three groups of pathologic factors presented—ulcer, cancer and pernicious anemia—showed, in the order stated, progressively increased degrees of change in the muscularis mucosae.

The grading of gastritis revealed relatively more severe gastritis at the pylorus than at the fundus in cases of duodenal ulcer, gastric ulcer and carcinoma with free hydrochloric acid. In the remaining groups gastritis was equally severe in pyloric and fundic sections.

There was very little difference in the degree of gastritis noted in carcinoma with and without free hydrochloric acid. In general, the lesions associated with the group in which free acid was still present were smaller than those in which achlorhydria was present. If the gastritis was the result of carcinoma, one might expect to find more severe gastritis in the latter group. The findings in this study are by no means conclusive but appear to be compatible with the possibility that gastritis preceded the carcinomatous lesion.

After consideration of these findings it would appear to follow that histologically the degree of gastritis lends itself well to grading on the basis of 1 to 4 by use of the previously described criteria. The status of the muscularis mucosae is an especially valuable critical unit of grading, since the degree of cellular infiltration, fibrosis, splitting and fragmentation is a fairly reliable indication of the chronicity of the inflammation.

The author hesitates to venture an opinion as to whether gastritis is a precursor to peptic ulcer or carcinoma, since the extent of this study does not warrant it. However it does appear that gastritis is the same in whatever pathologic condition of the upper portion of the gastrointestinal tract it occurs. It begins with an inflammatory reaction accompanied by hyperemia and cellular infiltration. If chronicity is allowed to develop by virtue of persistence of the

etiologic factor the mucous membrane passes through successive stages of glandular destruction erosion formation of cysts destruction of the muscularis mucosa and finally a state of atrophic anadenia. All the while this is going on, the glandular elements which still persist make sporadic attempts at regeneration in an effort to regain normal function but finally fail and are replaced by an intestinal type of mucous membrane. The end result is the same, be the associated condition ulcer cancer or pernicious anemia.

Experimental Research on the Behavior of a Loop of Intestine Isolated from its Continuity with the Remaining Intestine and Proper Mesentery (Ricerche sperimentali sul comportamento di un anca intestinale isolata dalla continuità col rimanente intestino e dal proprio mesentero) RINO BALDELLI. *Gior Ital chir.*, 1948 4 154

Adult dogs weighing from 15 to 18 kgm. were used for the author's experiments. Under aseptic precautions a loop of small intestine from 20 to 25 cm in length was invested with omentum and placed through three avascular areas in the mesentery. The serosa was roughened in the involved area. After from 25 to 30 days a second operation was performed in which all of the blood vessels in the mesentery leading to the involved loop were ligated. The loop was then resected at its ends and the two openings were sutured to the skin and abdominal wall thereby being exteriorized. An end-to-end anastomosis was then made to re-establish the continuity of the remaining intestine.

After 9 months a third operation was performed when the isolated loop was resected and a normal segment was also resected for comparison. Following this the dog was returned to normal life.

The author after making a careful study arrived at the following conclusions:

The isolated loop with external openings maintains an open lumen which can be demonstrated by injecting either end with a liquid as it will escape from the other end. This can also be demonstrated by injecting some barium and then taking roentgenograms.

Histologic examination of the resected loop shows that it maintains itself perfectly conserving unaltered the relations and structure of its various tunics and their elements.

The adhesion of the omentum to the intestinal wall is perfect and results in the formation of vessels easily visible.

With the two openings of the isolated loop being exposed it is possible to study the physiology and pathology of this loop and also its behavior under different stimuli. (The author is now conducting research along these lines.)

It is noted that this isolated loop being attached only to the omentum and therefore freely mobile could readily be employed for plastic purposes at a distance from its source.

LEON J. FRODUCT M.D.

Acute Intussusception in Childhood BRENDA MORRISON and DONALD COURT. *Brit M J* 1948 1 776.

A detailed study was made of 100 children who were treated for acute intussusception from 1944 to 1946 and it has been shown that the family doctor who first sees the patient has the major responsibility for the end results. In the past 30 years the mortality has fallen from nearly 40 per cent to less than 10 per cent. It is below 5 per cent for children treated in the first 24 hours but rises steeply to 20 per cent or more when the disease remains untreated for more than 2 days. Time is therefore an important and often a vital element in this disease. In the present study the authors have considered the exact duration of the illness, the time at which the different symptoms and signs made their appearance, the time the doctor was called and the time at which the child reached the hospital.

Of the 100 cases there were 83 in which accurate time intervals were known. 66 of the children were seen by a doctor within the first 24 hours but only 34 (41%) were admitted to the hospital within that period. Of the 80 children who were seen within 48 hours only 53 had reached the hospital at the end of the second day while the admission of the remainder was not completed until the seventh day. This delay is culpable in view of the increasing mortality after the second day. It suggests that the problem of acute intussusception is not primarily that of improving the method of treatment but rather the ability to suspect the disease within the first 24 hours and ensure prompt hospitalization.

A description of this disease is found in most textbooks. It has in general followed a history wherein a healthy well nourished male child at 9 months or shortly thereafter develops severe abdominal pain with pallor and collapse. The pain recurs at intervals of about one half hour and spasms persist from a few seconds to a few minutes. Vomiting may occur though it is not an important symptom. Apart from an initial stool constipation to obstipation is the rule although within a variable unspecified interval dark red blood resembling currant jelly is passed per rectum at which time the diagnosis should become apparent. The first signs are usually conclusive but the first day of illness may yield little evidence. Pallor, quietness, limpness, rapid pulse rate, restlessness, loss of skin tone and other signs of dehydration become more evident on the second and third day. Finally, the baby presents a desperate picture: anxious, gray, cyanotic, listless, restless movements of the head and limbs, coldness and blueness of the extremities and the final stage of complete peripheral circulatory failure. Fever is usually present even on the first day of the disease. The abdomen is difficult to palpate because of the resistance induced by tenderness. Once obstruction is established the distention may make it difficult to feel a mass but in a collapsed baby the tumor may be felt with the greatest of ease and little or no protest. This mass is (as has been well described in most accounts of the disease) cylindrical or

sausage-shaped and lies somewhere in the line of the colon, except in the ileocolic invaginations. Rectal examination should never be omitted. It shows (1) the presence of blood on the finger or its passage after examination (2) the direct palpation of the apex of a low intussusception, and (3) the empty even ballooned condition which is present in many cases but requires experience for recognition.

A diagnostic barium enema is scarcely ever required for the diagnosis of acute intussusception. However, enemas have their proper use in the investigation of suspected subacute or chronic intussusception.

With regard to treatment the authors state that since acute intussusception is a serious emergency and so many different medical functions are involved such as diagnosis, resuscitation, anesthesia, operative surgery and general pediatric care there will be divided authority and responsibility. It is therefore essential for treatment to be in the hands of a team, each member of which knows his part and the extent of his responsibility. It is, however, better to have a pediatrician responsible for the conduct of the case.

Preoperative treatment consists essentially of the treatment of shock and dehydration. It is risky to leave transfusion until the end of the operation when the patient may be irreversibly collapsed and the technical difficulties greatly increased by peripheral circulatory failure and the empty veins. The transfusion of blood and saline preoperatively is recommended. Satisfactory anesthesia both during and after the operation the length of the anesthesia being reduced to a minimum is important. Since these babies tend to vomit during operation a nasal catheter should be passed into the stomach preoperatively and left in position to assist first the anesthesiologist and later the pediatrician.

Because circulatory collapse can occur immediately after operation these patients require constant supervision in the operating room, on the way back to the ward, and in the ward by someone experienced in resuscitation and able to take the decisive action required. Prompt clearing of the airway, oxygen, the prevention of vomiting and aspiration by gastric suction, all may be necessary.

A review of the end results indicates that the time element and early operative interference are of major importance. SAMUEL J. FOGELSON, M.D.

Duodenitis (Duodenite). G. SORTIN. *Arch Ital med exp diger* 1943, 4: 3.

The term duodenitis has significance anatomically and radiologically but it has little or no significance clinically.

Of the different forms of duodenitis those due to such causes as tuberculosis, lues and burns are rare and of limited interest. Other forms, of uncertain pathogenesis, are seen more frequently.

Duodenitis may be of inflammatory or noninflammatory origin. The noninflammatory type may be a glucocortic, allergic, pseudomucous or dystrophic.

The lesions are probably initiated by dysfunction of the gastroduodenal mucosa, and are referred to as a pseudoinflammatory condition. The noninflammatory lesions present a primitive ulcer of neurovascular origin, differing from the inflammatory or erosive type of ulcer in that it penetrates the muscularis.

Duodenitis is frequently associated with gastritis, and is rarely present alone. It may also be secondary to appendicitis, catarrhal hepatitis, pancreatitis, or splenitis. Once these associated lesions initiate the duodenitis it may automatically become chronic.

The clinical forms of chronic duodenitis without ulceration are recognized as pseudoulcerative, hemorrhagic, dyspeptic, subicteric, pseudocholelithic, and pancreatic.

The diagnosis is based on the clinical and roentgenographic findings and on aspiration of the duodenal fluid. The symptoms are simple dyspepsia with duodenal pain after meals, associated with nausea. On aspiration of the duodenal contents, the amount of albumin must be determined while low value is placed on the quantity of mucus, the acid ferments and viscosity.

Therapy is the same as for chronic gastritis, mostly symptomatic and etiopathogenetic, with stress on the use of hydrated mineral. Surgical treatment must be considered as the lesion is both ulcerative and hemorrhagic.

ARTHUR F. CIPOLLA, M.D.

The Surgery of Duodenal Ulcer. CHARLES WELLS and A. C. BREWER. *Brit J Surg* 1948, 35: 384.

The authors report their observations, and discuss fully the indications for operation in patients with resistant duodenal ulcer. Their argument is based on a personal experience with 363 patients, all of whom were submitted to operation. A variety of operations were performed and a number of patients underwent several operations. There were 5 postoperative deaths. All operations were performed in the 10 year period from 1935 to 1945 and for reasons explained in the text, only 800 cases have been traced on recent surveys. Although this number is apparently inadequate, the authors have found such a striking contrast in the late results following different types of operations that they feel justified in drawing very definite conclusions.

Following subtotal gastrectomy the results have been satisfactory in so near to 100 per cent of the cases that it is believed the operation may be recommended with the maximum confidence and a minimum of the guarded reservation with which it has in the past been necessary to approach the subject.

Certain definite conclusions have been drawn concerning the physiology of the stomach and the steps which it is necessary to follow in order to be sure of achieving a good result.

The authors describe in some detail their own preoperative, operative and postoperative procedures. They recognize that there are alternatives and have thought it advisable to make their meaning perfectly clear even to the extent of possibly

tedious detail. In spite of the low mortality recorded it is believed that this operation is neither a very easy nor a very safe one and that it should be attempted only under the best conditions. In particular the authors recognize that they have been fortunate both as to their anesthetists and anesthetics and that these factors are important in keeping at a minimum the incidence of dangerous chest complications.

JOHN J. MALONEY, M.D.

Chronic Hypertrophic Stenosing (Pseudotumoral)

Tuberculosis of the Ileum (La tuberculose hypertrophique chronique sténosante (pseudotumorale) de l'iléon). FROELICH, FRUEHLING and KISEL. *Nicksa. J. chir.*, Par 1948, 64, 88.

In chronic intestinal tuberculosis the amount of fibrosis surpasses often by far the development of caseation and leads to obstruction of the intestine so that it may easily be mistaken for a tumor. Such obstruction is of frequent occurrence in the colon (especially in the cecum) but occurs only rarely in the small intestine.

The authors present 2 cases, one of which is of special interest: a woman of 47 years without any history of tuberculosis gradually developed vague gastrointestinal symptoms, especially pains in the epigastric region after meals. She was treated for peptic ulcer for a period of 5 years, although no x-ray examination was ever done. Finally her complaints became much more severe. Diffuse colicky pains and frequent emesis occurred after the slightest intake of food and the patient became cachectic. At this time roentgenograms revealed an obstruction in one of the lower loops of the ileum. At laparotomy, 2 obstructing tumors the size of a prune were found and the involved part of the ileum was resected. Histologically the tumors proved to be large tubercles with very little caseation and marked fibrosis. The patient recovered completely after the operation and had a gain in weight of 25 pounds. This case is remarkable not only because of the rare localization of tubercles in the ileum but because no other signs of tuberculosis could be found in the patient.

WERNER M. SOLMITS, M.D.

The Postoperative Serum, Sulfonamide, and Antibiotic Treatment of Appendiceal Peritonitis (Die postoperative serum-sulfonamid und antimikrobiologische Behandlung der Wurmfortsatzperitonitis). W. RYFFEL. *J. internal chir.* Brux 1948, 8, 656.

This analytical study of over 500 cases of appendiceal peritonitis observed at Thurgauischen Kantonsspital, at Münstlingen demonstrated that the mortality rate was not significantly lowered by the use of antitoxic serum or by sulfonamide therapy. In those cases of appendiceal peritonitis in which no special postoperative treatment was administered the mortality rate was 14 per cent, in those patients receiving antitoxic coliform bacillus serum the mortality rate was 13.8 per cent, while in 137 patients treated with sulfonamide therapy 12.4 per cent had a fatal outcome. A small number of

patients treated with penicillin are not included in the statistics.

Bacteriological studies showed that the coliform bacillus was the causative agent in appendiceal peritonitis, neither the bacillus enterococcus nor the bacillus perfringens were of practical etiological importance. Cultures of coliform bacilli were drawn from the abdominal exudate, and the sensitivity of the organisms to the sulfonamides was evaluated. In every case the sulfonamides retarded the growth of the coliform organisms but the power of inhibition varied according to the variety of the bacillus coli. In certain cases the bacteriostatic power of the sulfonamides offered some assistance in the recovery of the patient, while in others the failure of such chemotherapy was confirmed by *in vitro* experiments. The injurious action of the sulfonamides on the liver must always be kept in mind.

The contradictory reports in the literature on the use of serum therapy in appendiceal peritonitis can be explained by the infinite number of varieties of the organism and of its endotoxins and the consequent impossibility of preparing a coliform bacillus serum which is sufficiently polyvalent. Any success attributed to its use is entirely fortuitous.

Contrary to general belief there is a relatively large number of coliform bacilli which are penicillin-sensitive, particularly among those found in pathological processes and which can be cultured freely *in vitro*.

ORVILLE F. GRIMES, M.D.

Chronic Ulcerative Colitis. WALTER LINCOLN PALMER. *Gastroenterology* 1948, 10, 767.

In 1 or 2 per cent of cases of chronic nonspecific ulcerative colitis there may be an acute fulminating course leading to death within several weeks or months. The rectum and rectosigmoid are usually initially involved and the disease may advance up the bowel in a retrograde manner. However, in the author's experience the initial extent of the disease as shown by roentgen examination is usually the maximal extent. Thus in 30 of 46 patients who were followed for a period of years, the extent of the disease did not change. In 11 patients the disease progressed and in 5 it regressed. Proctoscopic evidence of the disease was found in 97 per cent of the patients, involvement of the rectum and sigmoid was demonstrated in 58 per cent, and of the entire colon in 30 per cent. The segmental form of the disease without rectal involvement was found in only 3 per cent of the cases. The extent of the disease and the severity of the symptoms are not necessarily proportional. In the diagnosis of chronic ulcerative colitis the characteristic changes in the rectal mucosa is of utmost importance. The author states that in about 2 per cent of the cases with secondary inflammatory polyposis malignant changes developed.

There are two main theories as to the etiology of this disease. Some authors believe it is caused by infection, others believe it to be of psychogenic ori-

gun. The author believes the possibility still exists that ulcerative colitis may be initiated by a specific infection and perpetuated by other organisms. Both dysenteric and amebic colitis may be transformed into the nonspecific type. The author states that he has twice seen the transition proctoscopically from amebic ulceration to the nonspecific type—a substitution of bacterial inflammation for a parasitic one. If this concept is valid many organisms may be involved: enterococci, colon bacillus, *Bacillus necrophorus*, or a virus may be implicated. There can be no doubt that emotional stress may produce hypermotility of the bowel with resulting diarrhea, and the author presents several case reports illustrating the profound influence of emotional factors in some cases of ulcerative colitis. It may be that hypermotility, no matter how induced, may lower the resistance of the mucosa to infection and bacterial invaders of undetermined type may then produce the disease.

Physical rest is of great importance in the treatment of the disease. The diet should be of low residue relatively nonlaxative, high in calories and proteins. Supplementary vitamins may be given as needed. Parenteral amino acid and glucose feedings may be of great value in the acute phases. Antispasmodics such as belladonna and sedatives are helpful. If hemorrhoids are present operation is usually contraindicated. The author states that it is difficult to evaluate the effect of the sulfonamides and the antibiotics. In certain cases the sulfonamides or penicillin may be very successful, which would suggest the belief that different organisms may be involved.

The author has had only limited experience with streptomycin. Psychotherapy may be helpful in some cases, harmful in others. The chief indication for surgery in ulcerative colitis is intractability. Only 12 per cent of the author's cases have been referred to surgery for ileostomy with or without resection of the colon. Of the author's 141 patients, two-thirds have been able to get along quite well, 72 with medical management only and 50 after ileostomy with or without partial colectomy. Only 5 per cent of the patients have been cured, by which is meant absence of symptoms for 5 years with normal mucosa on proctoscopic and roentgenological examination. F. J. LIESCHAU, JR., M.D.

Surgical Treatment of Ulcerative Colitis. RICHARD B. CATTILL and ELMERT SACRA, JR., *J. Am. M. Ass.* 94:5, 37, 939.

During the 20 year period from 1927 to 1946 inclusive, 636 patients with ulcerative colitis were seen at the Lahey Clinic, Boston. One hundred and sixty-six patients (26%) were operated upon. During this period a plan of surgical management, spearheaded by earlier surgical intervention in the course of the disease has been evolved.

The operations are confined to three procedures: (1) ileostomy, (2) subtotal or partial colectomy and (3) total colectomy. The indications for surgery are thoroughly discussed and may be listed:

Failure of medical management. Patients in this group are those suffering with the acute fulminating type of disease which early tends to perforate the bowel or cause death from the toxemia of infection. In these patients, an ileostomy should be performed within a few days or a week after medical management begins to fail. In the chronic type of disease in which medical management fails the authors indicate operation on any patient who is incapacitated for 3 or more months out of each year. Also, patients with unsatisfactory nutritional states, persistent diarrhea or incontinence of the anal sphincter due to the disease can be greatly improved by operation.

Sabcutaneous perforation, abscess, and fistula. Free perforation of the bowel contraindicates surgery. Operation is done before perforation occurs when there are signs and symptoms of peritoneal irritation. Abscesses and fistula can be remedied only by surgery.

Obstruction. Contraction or stricture of the colon and rectum appears late in the course of the disease, and is a clear indication for surgery.

Hemorrhage. This is a rare complication of ulcerative colitis, but when it occurs operation should be advised. Patients with hemorrhage tolerate no resection, and operation is limited to ileostomy.

Infectious arthritis. Dramatic recovery from ankylosed and incapacitating infectious arthritis of one or more joints results from early removal of the diseased colon.

Polyposis. A pseudopolypoid degeneration of the mucosa may occur and is seen frequently in patients suffering from hemorrhage. These patients also respond poorly to medical management and should have surgical resection.

Carcinoma. In a recent review by the same authors it was found that the average duration of disease in 12 patients in whom malignant degeneration developed, was 9 years. This represents 7 per cent of patients previously operated upon and emphasizes the need of following these patients who have had ileostomies, clinically and roentgenologically for a long postoperative period.

Segmental colitis. In the small percentage of cases in which ulcerative colitis is limited to a small segment of the colon or rectum a segmental resection and anastomosis may be done. However these patients must be carefully selected to demonstrate a limited process in the areas to be resected; else recurrent disease will create a greater surgical problem.

As to the type of operation, ileostomy is usually done first, thereby putting the colon at rest while the patient is observed for a period of 6 months. During this time maximum improvement should be evident on sigmoidoscopic and barium enema examinations. There are three possibilities for the patient who has had ileostomy. First, the ileostomy may be closed. In a few cases of complete remission of symptoms, for a year or more after ileostomy and negative sigmoidoscopic findings and an adequate lumen, as demonstrated by the barium enema, must all be present. Second, the ileostomy may be permanent with continued remission of symptoms. Colectomy

is not indicated in these cases. Third the ileostomy is permanent but symptoms continue and colectomy must be done for relief. About one third of these patients have a partial colectomy and about two-thirds, colectomy and abdominoperineal resection carried out in two stages.

The authors present and discuss their statistics over a 20 year period. The trend toward earlier and more frequent surgical intervention with an improved mortality rate of 4 per cent in the past 75 patients is indicated. JAMES C. MACMILLAN, M.D.

Colectomy in Megacolon (De la colectomie pour megacolon) JEAN QUÉNU *Mém Acad chir. Par.*, 1948, 74, 195

Only after long postoperative observation is it possible to arrive at a correct evaluation of the success of colectomy. In some patients there is gradual improvement for years after surgery whereas in others the initial excellent results are only temporary.

The author discusses his observations in 19 per cent cases in which colectomy was performed the first, 78 years, and the latest, 2 years previous to the present report. All of the patients were adults.

As to the choice of operation the author is much opposed to ileosigmoidostomy and typhlosigmoidostomy which give poor results. Colectomy of the sigmoid gives excellent results provided that the megacolon is limited to the sigmoid. If other parts of the colon besides the sigmoid are involved total colectomy is preferable to all other operative methods. The author has performed this formidable operation six times. Two of the patients succumbed to the operative shock of the 4 surviving 3 had good to excellent results.

The author admits that his experience with neurosurgery for the treatment of megacolon is limited however before deciding in favor of total colectomy he performed infiltration of the lumbar sympathetic in all cases and only when this procedure did not meet with success was total colectomy done.

WERNER M. SOLMITZ, M.D.

Megasigmoid. Clinical and Surgical Considerations in 36 Cases (Megasigma. Consideraciones clínicas quirúrgicas sobre 36 casos) ABEL N. CANÓNICO and FEDERICO R. PILHEU *Revista med. argent.* 1948, 35, 484.

Canónico and Pilheu studied a series of 36 cases of megacolon involving only the sigmoid area. They found 66 per cent of the patients to be between 30 and 60 years of age and also that this condition was twice as frequent in males as in females. The most frequent symptoms found were constipation and obstruction. The frequency of complications suggested that the condition is not to be regarded as merely benign. Obstruction due to volvulus or fecal impact was present in 13 patients 4 of whom underwent emergency operations. The barium enema examination is regarded as the most precise method of diagnosing the condition of megacolon.

Medical treatment was used with advantage in patients with mild difficulty in the progression of the feces. Surgery is considered the elective treatment in advanced and in complicated cases. In huge megasigmoid when there is no possibility of recuperation of the intestinal motor activity in cases with repeated episodes of mild intestinal obstruction and when the medical treatment has failed to relieve frequent fecal impactions.

The author with the aid of excellent illustrations, analyzes the results obtained both by the medical and surgical treatment. The surgical treatment used was variable: manual extraction of the fecal impaction; segmentary resection with end-to-end and lateral anastomosis; Mikulicz resection; total colectomy and sympathectomy. Of 30 patients who were operated upon only 4 died.

WILLIAM E. RICKETTS, M.D.

Which Is the Better Surgical Treatment for Cancer of the Rectum? (Qual è il miglior trattamento chirurgico del cancro del retto?) TEORILLO BIANCHI *Chirurgia*, 1948, 3, 19.

After studying 122 subjects operated on for carcinoma of the rectum, the author formulated the method of cure to be followed.

Of the 122 patients whose cases are reported, 72 per cent were men and 28 per cent were women. Eighty five per cent of the patients were between the ages of 50 and 70; the youngest patient was 23.

A radical operation was done on 86 patients with an over-all mortality of 10 per cent. Among 40 patients on whom an abdominal perineal amputation was performed the mortality was 10 per cent. Among 33 patients on whom perineal resection alone was done there was a 21 per cent mortality. Of 13 patients who were treated by abdominoperineal resection with conservation of the sphincter all survived. The greater mortality in the group upon whom perineal resection alone was performed was due to the fact that these patients were poorer risks than the others. Of 36 patients on whom a colectomy was done because the carcinoma had already metastasized the mortality rate was 27 per cent.

The author advocates a transverse colectomy in inoperable cases. When the tumor is less than 5 cm. from the sphincter he prefers a perineal or an abdominoperineal amputation depending on the degree of involvement. Abdominoperineal resection with conservation of the sphincter is indicated in those cases in which the tumor is greater than 5 cm. from the sphincter. Conservation of the sphincter for the betterment of the social life of the patient is stressed.

Complications such as infection of the perineal wound, fistulas and stenosis at the anastomotic site were infrequent.

ARTHUR F. CIPOLLA, M.D.

Spasm and Fibrosis of the Sphincter Ani Due to Reflex Action FRANCIS C. NEWTON and CHARLES A. MACCORMOR. *N. England J. M.*, 1948, 339, 113.

The authors describe a clinical entity of spasm and fibrosis of the sphincter ani with marked constipation.

tion, chronic excessive use of cathartics, and vague symptoms of abdominal discomfort anorexia cramps tenesmus, and flatus.

It is much more prevalent among women having occurred in 19 of 21 patients reviewed possibly because women lead a less active and more sedentary life than men and are thus more prone to constipation. The average age was 55, and all but two of the patients had taken daily cathartics for a period of years. A few patients had rectal bleeding but no rectal prolapse was encountered.

Physical examination always revealed a marked degree of spasm of the anal sphincter. Both the internal and external sphincters were found to be spastic hypertrophied hard, and hyperirritable. Moreover in most cases, the internal sphincter was definitely smaller in diameter than the external sphincter.

Treatment consists of anal dilatation under a general anesthetic. Dilatation should be carried out slowly to avoid tearing of the muscle fibers with resultant hematomas and fibrosis. The time required is usually 10 minutes or until one is able to insert a total of four or five fingers to their full depth with ease. Frequently one is forced to partially incise the external sphincter in the midline posteriorly because of a shelllike hypertrophy or even fibrosis of the tissue. Hemorrhoidectomy, excision of a polyp or curettage if a fissure if indicated should be done at this time.

In patients in whom surgery is performed the postoperative diet should consist of clear fluids with out milk for a period of 4 days then a gradual return to a normal high-residue diet without cathartics. If no abnormality other than spasm is found a high-residue diet without cathartics may be resumed immediately. In uncomplicated cases, rectal dilatations should begin on the fourth day and be performed daily either digitally or by the use of graduated Young's dilators. Dilatation should be continued as long as it is required to re-establish normal bowel habits and can be done by the patient himself.

ELY ELLIOTT LAZARUS, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Intravenous Cholecystography with Tetraiodophthallic Fluorescein. GEORGE E. MOORE and MARION J. SMITH. *Surgery* 94B, 24, 7.

The advantages of intravenous cholecystography are very real in contrast to dye administered per os. A known quantity of dye is injected directly into the blood stream, the variable factor of intestinal absorption is circumvented and the interval before the gall bladder can be visualized is shortened. For these reasons the authors believe that the report of an additional dye for intravenous cholecystography would be of interest.

Tetraiodophthallic fluorescein has a low toxicity great solubility, and contains 57.7 per cent of iodine. Following its administration there were no instances

of vomiting or diarrhea. All the patients were tinted a light flesh-pink color by the dye and this color remained visible in the skin for several hours, but then disappeared.

The technique consists of rapid intravenous injection of approximately 40 mgm./kgm. of body weight, so that the total dose given adults ranges from 2 to 3 gm. The dye solution is adjusted so that 15 c.c. contain an individual dose. Preparation of the patient is negligible and only a light fat-free breakfast given the morning of the examination is necessary. The first roentgenogram is taken 2 hours after the injection of the dye. If this showed a gall-bladder shadow a fatty meal was administered and a second view (40 minutes later) was taken to show the contractility of the organ. If a poor or questionable shadow resulted at the time of the first picture, an additional roentgenogram was made in 3 hours. Oblique and upright views were obtained if necessary.

Subjective evaluation of the gall bladder shadows produced on the films showed densities comparable to those of tetraiodophenolphthalein.

ELY ELLIOTT LAZARUS, M.D.

Acute Cholecystitis. J. W. BARKEDALE and J. HARVEY JOCKSON. *Ann. Surg.* 94B, 187, 816.

The authors consider that the mortality of acute cholecystitis would be significantly lowered if conservatism in treatment, especially early in the course of the disease were less in vogue. In their opinion, the education of physicians in general to regard acute cholecystitis as being as much of a surgical emergency as acute appendicitis would result in a reduction of as much as one-half the present morbidity and mortality.

Obstruction of the cystic duct is believed to play a primary role in the pathogenesis of acute disease of the gall bladder. This is usually due to stone although inflammatory edema or congenital malformation may occasionally be encountered. In 80 to 90 per cent of cases the obstruction is relieved by dislodgment of the stone into the gall bladder or by its passage into the common duct. In 10 to 20 per cent of cases, however, there is no relief of the obstruction and as the intravesical tension increases with secretion, transudation, and exudation, vascular interference progressively ensues and leads to ultimate gangrene and perforation.

Conservatism, it is argued, is fraught with danger because the clinical findings in many cases do not parallel the severity of underlying pathologic changes. The authors are in agreement with the view that there is no such thing as a "silent" or "harmless" gallstone since the future course is unpredictable. With persistent failure of visualization by the Graham-Cole test, even in the absence of positive or negative shadows, surgical extirpation is advised since 90 per cent of patients will be found to have biliary calculi.

Although the authors believe that surgery is urgent, they recommend strict individualization of cases. From 4 to 8 hours of preoperative preparation

to re-establish fluid and electrolyte balance are thought to be in order. Sedation nasogastric suction and, frequently transfusion should be used. The initial 72 to 96 hours is the optimum period for surgical intervention. From the third or fourth to the tenth day after onset is regarded as the period of advanced disease—the time of systemic depletion impaired hepatic function and local complications such as pericystic abscess and peritonitis—and surgery is indicated during this period only if the disease fails to subside or progresses. Cholecystostomy is often the procedure of choice and should be done without apology for a safe drainage is infinitely better than an heroic excision. It is believed that such advanced cases are due to neglect, procrastination and wishful waiting and could have been avoided by definitive surgery at an earlier period.

WAYNE FIELD CAMERON M D

End Results of Unilateral Splanchnicectomy for Hypotonic Conditions of the Bile Ducts (Résultats éloignés de la splanchnicotomie unilatérale dans le traitement des états d'hypotonie des voies biliaires)
P. MAILLET GUY and M. JAUBERT DE BEAUJEU
Lyon chir., 1948 43 157

Since the first splanchnicectomy which was done for hypotonia of the biliary tract in 1941 the authors have performed this operation in a series of 112 cases. In the first group of 22 cases the operation was done for atony of the gall bladder diagnosed from cholecystographic findings without radiologic or manometric control during the operation. In most cases a test infiltration of the splanchnic nerve was used. The clinical symptoms included attacks of biliary colic constant pain in the right hypochondrium slow difficult digestion distention and constipation as well as lassitude migraine irritability and loss of appetite and weight. The results of operation were good to perfect in 22 cases fair in 1 case and poor in 2 cases. The failures emphasized the unreliability of cholecystography alone as a method of diagnosis without per-operative manometric and radiologic control.

In the second group of cases were 11 patients with atony of the gall bladder in whom the condition was diagnosed by manometric and radiologic control during operation. In the entire group of 33 cases of atony of the gall bladder the results were favorable in 21 of 23 cases which were followed up for 2 to 5 years, as well as in 6 cases followed up for less than a period of 1 year. The criteria of improvement include the disappearance or amelioration of symptoms. Since only one splanchnic nerve is resected these results cannot be due to interruption of the sensory paths. Many of these patients were able to resume their occupations, although a period of adaptation is necessary to attain maximum improvement. Postoperative radiologic studies show a return of tonicity of the gall bladder. A perfect result includes absence of objective or subjective symptoms restoration of normal tonicity of the gall bladder occasionally with complete evacuation. A very satis-

factory result includes only minimal persistence of symptoms. Results were reported as very good in 80 to 90 per cent, and good in 65 to 80 per cent of patients in whom no previous treatment had been successful. In one case novocain infiltration of the splanchnic nerve had a remarkable clinical and radiologic effect. Splanchnicectomy may thus be considered the operation of choice for atony of the gall bladder in the absence of infection parietal lesions and mechanical obstruction. It is emphasized that preliminary infiltration may falsify the results of per-operative manometry.

Once the decision to operate has been made one should verify the condition of the gall bladder and pancreas perform an extemporaneous bacteriologic examination of the bile, and a manometric and radiologic examination through the vesicular puncture orifice. If the diagnosis is thus confirmed a right splanchnicectomy may be performed through a lumbar incision.

Hypotonus of the common bile duct is a frequent cause of biliary disease. The roentgenogram shows a dilated common duct, without apparent peristaltic waves emptying passively through an abnormally gaping sphincter. The degree of dilatation varies widely. If it is very marked the common duct may also be elongated with kinking and tortuosity and may suggest dolichocholedochus. The atony of the sphincter may be so marked as to prevent reflux. It is necessary to distinguish between isolated atony of the common duct and diffuse atony of the biliary tract. When a direct measure of pressure in the choledochus is possible the results are characteristic and suffice for diagnosis.

In a third group the end results of splanchnicectomy for diffuse essential atony of the biliary tract are discussed. In 5 cases followed up for 2 to 5 years the results were good in all but one of 5 cases followed up from 1 to 2 years the results were very good and in 8 of 9 cases followed up for less than 1 year results were good. There was one postoperative death due to a unique and paradoxical complication namely marked gastroduodenal distention. This was attributed to resection of the external cornu of the semilunar ganglion which has since been avoided. Failure in one case with persistence of symptoms was due to a pancreatic condition and in another case mild symptoms recurred after 3 years of perfect cure. Good results were obtained in 6 cases of atony of the common duct following cholecystectomy in 6 cases of atony of the common duct associated with calculous cholecystitis and in 3 of 4 cases of atony of the common duct associated with disease of the cystic duct.

Finally in a fifth group of cases the authors discuss the results of splanchnicectomy in chronic pancreatitis associated with atony of the biliary tract. In 2 cases the condition was associated with vesicular atony without involvement of the common duct. In 20 cases atony of the common duct was associated with important pancreatic lesions as revealed by palpation and biopsy as well as clinical observation.

which revealed induration and the vertigo of acute pancreatitis. Both conditions responded to splanchicectomy.

From the results obtained, the authors conclude that splanchicectomy in cases of associated biliary atony and pancreatic disturbances should never be attempted if the condition of the bile tract appears doubtful. In such cases however splanchicectomy might yield good results following a derivation operation or an intervention restoring the permeability of the bile ducts. If the bile tract is otherwise normal, splanchicectomy is indicated and most especially when atony of the bile ducts has been demonstrated. Manometric and radiologic control during operation is imperative. EDITH SCHANCK MOORE.

The Accessory Pancreas Poising as a Benign Tumor of the Stomach (Das Nebenpankreas unter dem Bilde benignen Malignanten). DIETRICH VON KAISER. *Chirurg* 9:8 9 54.

In the last 10 years at the University Clinic in Jena 3 cases of roentgenographically benign tumors of the stomach have been observed. In all 3 cases the condition proved to be an accessory pancreas. Investigation of the world's literature revealed 106 cases of accessory pancreatic tissue in the stomach.

The clinical history in the 3 reported cases was suggestive of a chronic ulcer of the duodenum with pyloric stenosis. Abdominal pain and vomiting were the cardinal symptoms. The radiological study however was suggestive of a benign polyp probably without a true pedicle. A rounded filling defect was present, but the mucosal folds seemed undisturbed by this defect, and the peristalsis passed over it without any deformity of the contraction. The obvious reason for this is that the tumefactions in all of the patients were either in the submucosa or in the muscularis. In one instance the tumor was cystic and contained a clear straw-colored fluid.

All 3 patients were treated by gastric resection, and all were cured. The author believes that it is impossible to confirm the diagnosis clinically and that therefore an operation must be performed.

WILLIAM C. BECK, M.D.

Blood Diastase and Lipase Changes in Acute Pancreatitis. H. WAPENAW. *Brit M J* 9:8, 68.

The relative merits of two serum enzymes one for diastase and the other for lipase have been considered. The blood normally contains enzymes that are active on starch and vegetable oils. Their activity varies from person to person but is constant for each individual.

The diastase and lipase findings in 10 cases of acute pancreatitis are reported.

It was found that the two tests were equally satisfactory as indicators of acute pancreatitis. Their clinical application seems to be limited to the initial stages of the disease owing to the nature of the specific enzyme reaction. Evidence is given to show that serial diastase estimations may furnish information regarding the grade of severity of the disease.

JOHN J. MALONEY, M.D.

MISCELLANEOUS

Eighty-Seven Abdominal War Wounds (Sur 87 plaies abdominales de guerre). F. VAN VAKSEVELD. *Mém Acad. chir. Par* 9:8, 74. 60.

The author describes the organization and the activities of the surgical company of a medical battalion in the French Army. This unit, attached to an armored division, was organized and equipped for the development of the greatest possible mobility and for keeping as close as possible to the lines of combat. In one instance the company worked for a week at a distance of 800 meters (one-half mile) from the enemy positions in spite of terrific bombardment. The unit included a personnel of 150 individuals of both sexes, and 35 vehicles. It could be set up within 30 minutes and the equipment could be packed up and ready for march within 15 minutes. All wounded were brought to treatment in from a few minutes up to 2 hours after injury. As soon as they had recovered from the postoperative shock the patients were evacuated in heated cars provided with oxygen and transfusion equipment, most often 2 to 5 hours after surgery. The author believes that this early evacuation did not do any harm and is preferable to evacuation in the period between 12 and 48 hours after operation. During that time the danger of postoperative ileus and the lowered resistance of the intestinal sutures make evacuation and moving much more hazardous than in the beginning.

The follow-up examination of 87 patients with abdominal wounds revealed that 41 survived and 18 died; the fate of 28 was unknown. This comparatively low mortality of 30 per cent under battlefield conditions is attributed to the organization and perfect teamwork of the unit, early operation, generous transfusion of blood and plasma both preoperatively and postoperatively, the benefit of a highly skilled anesthetist, the local application of sulfanilamide powder (15 to 20 gm) and the postoperative injection of vitamin K in patients with liver injuries.

GYNECOLOGY

UTERUS

Rupture of the Uterus with Extraperitoneal, Mediastinal and Subcutaneous Emphysema Erik Ryssing. *Acta Obst Gyn scand.*, 1948 28 86

A 39 year old obese woman was admitted to the hospital during her sixth parturition. Previous labors had been normal. On roentgen examination a large fetus in breech presentation was demonstrated. Injections of pituitrin were given because of lack of progress in labor without any particular effect. Thirty-six hours after admission repeated hematemesis was noted and suddenly 6 hours later subcutaneous emphysema of the neck and cheek associated with severe dyspnea and cyanosis occurred. A macerated fetus weighing 6 000 gm was delivered by operative breech extraction followed by manual removal of the placenta. The patient died 11 hours after delivery.

Autopsy revealed an incomplete rupture of the uterus which had caused emphysema of the left parietum. The extraperitoneal air bubbles could be followed from the broad ligament to the retroperitoneal tissues into the perineal tissues into the lesser omentum and up to the mediastinum, neck, and cheek. The pathogenesis symptoms and treatment of emphysema are briefly discussed.

GEORGE BLINICK, M D

Changing Concepts in Cervical Biopsy KENNETH E. COX, VICTOR B. BUEHLER, and WILLIAM C. MITCHELL. *Am. J. Obst.* 1948, 56 112.

A series of 7 cases of equivocal lesions of the cervix is presented. The management is described. In a total of 110 routine biopsies 2 cases of intraepithelial carcinoma were found representing an incidence of 1.8 per cent. The incidence of intraepithelial and early invasive carcinoma in this series was roughly comparable to published statistics in routine hysterectomies in which the entire cervix was immediately available for study. It was about three times the incidence reported in a series in which additional tissue was not available for study. These comparisons have led the authors to believe that if the cervix were available for study in all cases in which equivocal lesions are discovered in routine biopsy, a far greater number of intraepithelial and early invasive carcinomas would be discovered than has heretofore been possible.

As a result of their study of this small series of cases the authors' concepts of cervical biopsy have changed. In the future biopsy will be considered as a screening process in those cervixes that present no grossly recognizable cancer. Cauterization of the cervix at the time of the original biopsy will be abandoned so that additional tissue for study will be available if necessary. The finding of equivocal lesions atypical metaplasia and possible intraepithelial

carcinomas will be followed routinely by complete sectioning of the original block and wide sectioning of the cervix. Frozen sections will not be taken. Conization will be performed with the scalpel rather than the cauterizer so as not to desiccate the specimen.

A registry of intraepithelial carcinomas of the cervix has been sponsored by the Central Association of Obstetricians and Gynecologists. The purpose of this registry will be the confirmation of diagnosis by competent gynecologic histopathologists and provision for adequate follow-up of these cases. It is believed that in the study of a lesion in the cervix the highest order of opinion with respect to its nature is still divided. Greater progress will be made by the concerted action of a group of gynecologists and pathologists than can be accomplished by individuals working alone.

JOHN R. WOLFF, M D

Mesonephric Remnants in the Cervix. JOHN HURTMAN. *Am. J. Obst.* 1948, 56 23.

The present article concerns the embryology, histology and the microscopic pathology of mesonephric remnants in the uterine cervix. The literature has been reviewed serially-sectioned tissues have been studied and sections from 1,192 surgically excised cervixes have been examined.

The presence of an ampulla of the mesonephric duct in the fetal cervix has been demonstrated by Meyer and others. A study of serially sectioned fetal uteri confirms their observations. Remnants of these fetal elements may persist in the adult cervix either as nondegenerated structures or as neoplasms arising from such residues. These remnants will ordinarily be discovered during the study of routine sections of the cervix. The characteristic histologic appearance of mesonephric remnants in the cervix is that of small tubules or canaliculi lined by a typical low columnar nonsecretory epithelium consisting of cuboidal cells containing a translucent pale cytoplasm and large well staining ovoid or round nuclei. These tubules can be differentiated from cerplasma arising from these remnants is described in detail.

Five cases of mesonephric remnants in the cervix and 5 cases of neoplasms arising from mesonephric remnants in the cervix are added to the literature. There is now sufficient evidence to warrant the acceptance of mesonephric duct remnants in the cervix as a histopathologic entity.

JOHN R. WOLFF, M D

Carcinoma of the Cervix. MANUEL GARCIA and LEON J. MONTVILLE. *J. Am. Med. Ass.*, 1948 137 1101

An analysis of radical surgical treatment and radiation therapy in carcinoma of the cervix is presented. With all methods of treatment there has been a sharp rise in absolute cure rate of 5 years survival.

equally with a decided drop in mortality. The salvage in the surgical group has remained unchanged since the early part of the century, while the salvage in the group treated by radiation has shown progressive improvement.

No one now uses surgical therapy exclusively. Instead the aim has been to afford each patient the maximum opportunity for recovery with minimum primary risk. In favorable cases averaging one-third of the material the patients are operated on and often irradiated too, while the rest are treated by radiation alone. This plan has been called 'elective therapy' by Stoeckel. 'Elective therapy' gives better results than those obtained during the strictly surgical era. Rigid criteria for operability, modern surgical technique and the advantages of general surgical progress have greatly reduced the mortality and complications from the operation.

Data are presented which show failure to control the disease surgically in one-third of the operative survivors as a result of recurrences within the pelvis 65 per cent appearing within 2 years.

The chance for recovery does not depend entirely on the histologic grade of the tumor. The operative mortality is higher in older women than in younger ones. The clinical and anatomic extent of the disease influences the patient's chance for recovery. Parametrial invasion is a sign of incurability.

In patients with metastasis to the pelvic lymph nodes the rate of curability after operation is decreased and the operative risk is increased.

Results are definitely improved when radiation therapy is added to surgical therapy. In addition preliminary irradiation reduces infection and the risk of peritonitis at operation.

Radiation was first used as a palliative agent in the treatment of advanced disease. In this respect it remains unrivaled and unchallenged today.

Radiotherapy carries a definite mortality risk; the principal one is exacerbation of sepsis.

Immediate morbidity is manifested in the form of radiation sickness, exhaustion or irritative phenomena in the skin, in the urinary and the intestinal tracts, and by a flare-up of latent infection. Various late sequelae may occur as injuries of variable severity such as ureteral obstruction, ulcer of the bladder, fecal prolapse, intestinal bleeding and obstruction and fistulas of the bladder, rectum or intestine.

In regard to permanency of healing, no significant differences can be demonstrated in the absolute salvage obtained by radiation and by surgical treatment after a period of 10 years. The ratio of 10 to 5 year survivors averages 75 per cent in each group. Such a finding is contrary to expectation; the ratio should be significantly higher in the surgical groups for obvious reasons.

The age of the patient and grade of the tumor have no consistent relation to the possibility of cure. However, serial biopsies of a tumor under treatment may constitute an important prognostic aid. Also, serial vaginal smears give a good indication of the reaction to radiation in the individual tumor. All series show

that the chance for recovery is inversely correlated to the extent of the disease as determined by clinical examination. Infection is a frequent and serious handicap to treatment and it significantly impairs the results. Although complete radiation therapy is not possible in all cases, for various reasons patients completely treated have the best chance for recovery.

It is impossible to obtain conclusive information on the effectiveness of radiation in the presence of metastasis to nodes. However from the data presented it must be concluded that preliminary irradiation does produce a definite effect and that some of the metastases are destroyed.

A number of authors have emphasized the fact that patients with carcinoma in its early stages should have the benefit of hysterectomy since the incidence of recurrences after irradiation is said to be high, and in about one fourth of the cases in which hysterectomy has been done following radium therapy apparently viable cancer cells are present. The presence of such cells is not significant, since the subsequent behavior of such cells is unknown. The only valid manner of testing the efficacy of treatment is by the 5 year results. In an analysis of 1,063 cases in stage I the results obtained with radiation therapy alone and those obtained with the combined treatment do not differ significantly. On the other hand, the salvage in the surgical cases is significantly lower than that obtained with either one of the other two methods. While the routine performance of hysterectomy appears to exert no definite improvement in results, there is no doubt that many lives could be saved if hysterectomy were employed promptly in technically and clinically operable cases in which the immediate effects of radiation prove unsatisfactory.

MISCELLANEOUS

Stress Incontinence. MORTIMER REDINGTON, *Br. J. Urol.* 1948, 20: 77.

The operation of urethroplasty for stress incontinence has gained an unfavorable reputation because of the high percentage of failures, assessed by some as high as 30 per cent. The author describes an operation which in his experience has been uniformly successful in 120 cases.

The cause of stress incontinence is unknown. However, two things are certain and constant: (1) that there is a sagging of the neck of the bladder and that stress incontinence may be cured by lifting the neck from this sagging position, (2) that the length of the female urethra in the living is much shorter than that in the cadaver. The author has found that the length of the urethra never exceeds one inch. The bore or width of the urethra has no influence on stress incontinence. It is not necessary to have a urethrocele, nor though the condition is very often associated with a cystocele, has the presence of a cystocele any influence on the condition.

The principle of the operation is as follows: The tissues between the urethra and the pubic bones,

Fig 1

Fig 2

Fig 3.

Fig 1 (Reddington) Removing ridge of tissue to begin urethral dissection. Fig 2 Dissection of urethra and neck of bladder. Fig 3 Freeing bladder from vaginal flaps in order to mobilize urethra and bladder neck.

acting as a finger on either side are brought under the neck of the bladder and the urethra, and in so doing displace these structures upwards under the pubic arch.

In order to do this certain conditions must be observed (1) the whole length of the urethra, from the urethral orifice and including the neck of the bladder, must be moved into this new position (2) the urethra and the neck of the bladder must be moved very decidedly at least one half to three quarters of an inch under the pubic arch (3) enough firm tissue must be brought under the urethra and the neck of the bladder to ensure holding these structures permanently in the new position (4) there must be free access to all the tissues concerned before these conditions can be fulfilled. The technique is best described in the accompanying illustrations.

The patient has difficulty in voiding the first 48 hours following operation. She is allowed up on the third day goes home on the twenty first day, and reports back at intervals of 1, 3 and 12 months. It is not considered wise to insert a self retaining catheter, nearly all of these patients require to be catheterized the first 48 hours.

Among a total of over 120 operations there were 2 failures and 2 partial failures, all in early cases in which the necessity for rigid adherence to the conditions laid down was not realized. The 2 patients in whom operation failed have since been cured following a repeat operation. The 2 others who experience leakage of urine only on great strain are able to lead normal lives and consider that the small remaining disability can be disregarded.

Stress Incontinence in the Female P. A. TREAHY and H. K. PACET *Austral. N. Zealand J. Surg.* 1946, 17, 227

The standard operative procedure for the correction of stress incontinence in the female consists of replacing the cervix, bladder and urethra into the pelvic cavity and holding these structures in position by various means, all of which in one way or another utilize the pubocervical fascia as support. The results following this procedure are not entirely satisfactory.

In stress incontinence urine escapes with a sudden increase of intra abdominal pressure. The quantity of urine ejected is directly proportional to the amount of force and with cessation of this force there is no dribbling. In the normal woman such leakage does not occur since there is an intact pelvic floor with the bladder so buttressed that a rise in intra-abdominal pressure prevents a sudden increase in intra-urethral pressure but with herniation of the bladder base and urethra through apertures of the pelvic floor (the common findings in cases of stress incontinence) the mechanism of this region are so altered that an abrupt pressure change is not dissipated over the pelvic floor but rather is concentrated in the hernia thereby forcing the sphincter with a consequent expulsion of urine. The bladder musculature plays a passive role.

The diagnosis of stress incontinence must be accurate. Cystoscopy should be done to eliminate an intrinsic bladder lesion. Then with a full bladder and the cystoscope withdrawn the meatus should be inspected for leakage or true incontinence. The patient is requested to cough and with stress incontinence a jet of urine spurts from the meatus. A finger on either side of the urethra supporting the base of the bladder will prevent loss of urine with cough. With the patient in the erect position a greater quantity of urine is ejected. Sphincter tone is ascertained by asking the patient to stop the act of micturition voluntarily.

The operation proposed is performed by the vaginal route. After an incision into the anterior vaginal wall the bladder is mobilized from the uterus and the pubocervical fascia. The entire urethra is mobilized up to the external meatus so that the seeking finger readily impinges on the pubis in front, and the ischio-pubic ramus laterally. Deep in the paraurethral fossa will be seen a white band of tissue the edge of the pubococcygeus muscle. This is stitched to the corresponding muscle of the opposite side with fine sutures of interrupted chromic catgut. The union is carried forwards until the foremost suture commences to compress the urethra and backwards until the gap of the bladder herniation has been obliterated. Prolapse is corrected if need be. The pubocervical fascia and vaginal wall are closed in the routine manner. Catheter drainage is maintained for about 10 days.

The authors cite 13 cases of patients so treated. All patients expressed satisfaction with the operative results.

WARREN R. LAM, M.D.

Genital Tuberculosis in the Female (Tuberculosis genital f. menas. Breves consideraciones clinicas) MANUEL URUTIA *Gac. Med. Mexico* 1945, 3: 130

Of 3,578 admissions on the gynecological service of the General Hospital in Mexico, there were 18 patients with genital tuberculosis, and 50 per cent of these had a primary active or inactive pulmonary lesion. Five per cent of all cases of salpingitis were tuberculous.

The tubes were found to be involved more frequently (in from 85 to 90 per cent of patients) than any other genital organ. Involvement of the tubes occurred through hematogenous spread from a distant tuberculous focus and produced a bilateral endosalpingitis and perisalpingitis with peritoneal, periovarian, and endometrial extension. The resulting forms of salpingitis are as follows: (1) interstitial, (2) nodular, (3) hydrosalpinx, and (4) pyosalpinx.

Extension of the tuberculous process from the tube to the uterus was seen in from 35 to 50 per cent of the cases with resultant endometritis (95%) or myometritis (5%).

The ovaries were invaded in from 25 to 45 per cent of the subjects and resulted in a perioophoritis, parenchymatous invasion or a tubo-ovarian abscess simulating suppurative gonococcal adenitis.

Rarely (0.5%) was the cervix involved. Extension to the vagina caused two forms of infection: (1) hyperplastic granular or (2) ulcerative.

Patients with genital tuberculosis usually complain of mild pain in the iliac quadrants. Frequently they are sterile and have the following menstrual disturbances: dysmenorrhea, menorrhagia, oligomenorrhea, and amenorrhea.

On vaginal examination of the patients in the author's series, there was pain on movement of the uterus associated with a painful adnexal mass of variable size.

Laboratory examination revealed an anemia with a variable leucocytosis. The sedimentation rate was increased, and a biopsy of the endometrium showed a typical tuberculous endometritis.

The author advocates an endometrial biopsy in all patients suspected of suffering from tuberculosis of the genitalia. In those with ascites a peritoneoscopy should be done and in those having tuberculosis of the cervix or vagina guinea pig inoculation is advisable.

ARTHUR F. CHOLEA, M.D.

The Labhardt Operation in the Treatment of Genital Prolapse in Elderly Women (L'opération de Labhardt dans le traitement des prolapsus génitaux chez les femmes âgées) J. MATHIEU *Ann. fr. Gyn. Obst.* 1945, 43: 2

In a series of 35 cases, the author reports his experience with the Labhardt operation for genital prolapse in elderly women. This operation consists of a subtotal colectomy in which the vaginal vault is left intact, and the vagina is reduced to a narrow suburethral canal barely admitting a pencil. This is accomplished by wide excision of the lateral and posterior mucosa, followed by suture of the freshened

perineum. The flap is formed by five incisions the first of which is almost circular about the vaginal orifice stopping on each side about 1 cm from the meatus. Two incisions parallel to the urethral tract are made with the bistoury. These incisions extend downward from the ends of the preceding incision for 3 to 4 cm. toward but not reaching the anterior cul-de-sac. Finally two incisions are placed down each side of the vagina terminating at about the middle of the posterior wall. In a second stage the mucosa thus circumscribed is liberated from the soft parts and resected. The author has found it simpler to liberate the flap as for repair of the posterior perineum after making a horse-shoe incision. Dissection proceeds beneath and in front of the mucosal excision which is accomplished with scissors. This technique facilitates rolling up of the suburethral mucosa to avoid its inclusion in the suture row groove. By approximating the posterior soft parts denuded of their mucosa, with several layers of transverse sutures of strong chromic catgut a resultant perineum is constructed having a thickness of 3 to 4 cm. and a height of 6 to 7 cm. This constitutes the fourth and last stage of the operation.

Preoperative preparation of the patient includes general supportive therapy and preparation of the vaginal mucosa by small doses of folliculin or synthetic estrogen. Low spinal anesthesia in small doses is preferable. In hypertensive patients general anesthesia is preferable. Also local anesthesia is possible but it should be used only as a last resort.

Following a comparison of the basic principles of the extended Lefort operation with those of the Labhardt operation the author demonstrates from a review of the literature that the decision to use one or the other of these two interventions cannot be based on their immediate results or end results. The two operations are not competitive but each complements the other. It is therefore the anatomic condition associated with the prolapse which must determine the manner of operation to be preferred in the individual case.

In prolapse following total hysterectomy the Labhardt operation is preferable because it is technically simpler than the Lefort operation and just as efficient. Also in cases complicated by urinary incontinence the Labhardt operation is preferable. In fact,

incontinence may be exacerbated by the Lefort operation.

As a rule however the decision as to which operation is to be performed can only be made after beginning the intervention and determining the anatomic type of the prolapse.

For third degree prolapse with extensification of the cervix, either one of the operations can be used. In such cases the author still employs the extended Lefort operation. In cases of asymmetrical prolapse with marked cystocele or rectocele the Labhardt operation is believed to be better. The same is true of prolapse through an atretic vulva. Finally in cases in which the tissues are badly torn the Lefort operation is indicated.

Thus by a happy coincidence the Labhardt operation proves most useful in conditions which do not respond so well to the Lefort operation and vice versa.

EDITH SCHANCHER MOORE.

Intestinal Changes Secondary to Irradiation of Pelvic Malignancies. JEROME M. MAAS *Am J Obst* 1948 56 249

Six hundred cases in which the patients received radiation therapy to the pelvic area for malignancies at the University of Wisconsin Madison, are reviewed. Transitory and permanent pathologic changes in the intestine were common. To insure adequate irradiation to a tumor of the pelvis certain irreversible changes must ensue. Radium is a more serious offender than are the x-rays. Higher doses of radiation therapy tend to produce permanent rectal lesions earlier and of a more serious nature.

In 523 patients radiation sickness developed. The onset and course of this condition are unpredictable and its management grossly unsatisfactory.

Proctitis is the most common of the permanent rectal diseases. The region of the rectosigmoid junction is the area most frequently involved. The onset and course of this condition are also unpredictable and its management is grossly unsatisfactory. The value of colostomy to check excessive bleeding or relieve obstruction is frequently negligible.

Rectal stenosis occurred in 48 cases. The process is irreversible. Rectovaginal fistula developed in 13 patients with spontaneous closure in 2.

Secondary carcinoma of the bowel occurred in 10 cases.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Research on Glucide Metabolism in Pregnancy
(Ricerca sul ricambio glucidico in gravidanza)
VARO GIRAR L. *Ginecologia Tor* 1948, 4

The author reports the results of his studies on glucide metabolism during gestation in a series of 102 subjects. Tracings of glycemic, adrenal and insulin curves demonstrated an intensification of the function of the insular apparatus concurrently with diminution of the metabolic activity of hepatic cells. The curves represented a total of 306 tests performed at various stages of gestation.

Two types of glycemic curves are recorded: the blood sugar level in fasting and sugar tolerance according to the method of Stanb and Traugott. Blood sugar determinations in fasting showed a slight but definite tendency to hypoglycemia toward the end of gestation.

Following the administration of glucose, hyperglycemia was accentuated in the early stages of gestation, gradually diminishing in the final stages of gestation. After the injection of adrenalin, hyperglycemia became less pronounced.

Following the injection of insulin, hypoglycemia was shown to disappear slowly and more slowly as gestation advanced. ALFRED F. CROZZA, M.D.

Anuria in Eclampsia (Anuria en la eclampsia. Su tratamiento eficaz por la novocaina intravenosa)
MIA ORTIZ RODRIGUEZ LÓPEZ. *Obst. g. lat-amer* 1948, 6, 44

Two cases of early postclamptic anuria are reported in which treatment consisted in the intravenous administration of 10 c.c. of 1 per cent novocain. The results were excellent and the patients had instant relief.

The author believes that eclampsia and anuria are the results of a vascular spasm in response to the internal secretions of the placenta; this transitory and paradoxical gland suddenly interrupted in the abnormal constellation of the permanent glands; the secretions of which the patient is unable to adapt himself.

First hypoxemia and then anoxia develop from the embarrassed circulation which later affects all the organs of the body and leads to degeneration and necrobiosis. The anuria is only the expression of renal vascular spasm at first functional and reversible but if allowed to continue it becomes irreversible and death may ensue.

Because of the premise that the condition is one of spasm, the treatment consisted of the application of a drug employed in other similar spasmodic conditions such as bronchial asthma, spasm of the retinal vessels (eclampsia amniotica), a mild distal lumbar. The administration of novocain should take

about 5 minutes and may be repeated in small doses every 6 hours. STEPHEN A. ZIMMAN, M.D.

LABOR AND ITS COMPLICATIONS

Face Presentation JOSEPH W. REDDOCK. *Am. J. Obst.*, 1948, 56, 86.

The results obtained in 160 cases of face presentation are reported. The frequency of face presentation in this series was 0.184 per cent. The condition occurred in multiparas three and a half times more frequently than in primiparas and mentoanterior presentations were more often seen than other positions.

Pain and its accompanying lack of abdominal and uterine tone were the most important etiological factors. Face presentation should be looked for in contracted pelvis and in patients with large babies. Brow presentations preceded complete extension of the head in 13 cases. Other factors, such as fetal neck tumors, hydramnios, placenta previa, small babies, compound presentation and the use of the hydrostatic bag in the first stage of labor probably predispose to face presentation and their presence should keep one alert for this condition. It appears that primary face presentations are not uncommon, there being 56 such presentations (among 160 patients) in which no explanation could be found for the condition.

Early diagnosis is important. Primary face presentations should be recognizable by careful abdominal palpation and vaginal examination with roentgenographic confirmation on if necessary. The important findings are concave dorsal plane, prominent small parts, loud fetal heart tones heard best through the anterior fetal chest wall, and the presence of a marked cephalic prominence on the same side of the baby as is the back, vaginally, the facial features are not to be confused with the breech.

Spontaneous delivery occurred from all positions and may be anticipated, provided there is no disproportion. In most multiparas and possibly a few primiparas, the latter group cesarean section should be done electively when the diagnosis is clear after fetal death and deformities incompatible with life have been eliminated. Low forceps to the face or following flexion of the head and manual rotation may be needed to finish the delivery late in the second stage. Versions and extractions should have no place in the delivery of face presentations except in an occasional case of a second twin which presents as a face.

It should be borne in mind that the long labors and difficult operative procedures necessitated by face presentations for vaginal delivery are the chief causes of maternal hemorrhage, infection, and fetal death. The adjusted infant mortality for this series was 7.3 per cent which could be materially reduced

by more carefully watched first and second stages omission of complicated vaginal procedures when simple procedures failed and substitution of cesar can section in these cases.

JOHN R. WOLFF M D

Symphysiotomy in the Antibiotic Era (La sinfisiotomía en la era antibiótica) ALBERTO PERALTA RAMOS. *Obst gín lat-amer* 1948 6 3

The author believes that symphysiotomy is the operation of choice in all types of cephalic presentation, inclination of the parietal bone under favorable conditions and in cases in which the presentation is strongly bearing on the superior strait (preferably embedded or modelled) as well as in the emergency breech presentation for extraction of the aftercoming head.

Symphysiotomy is apparently used more frequently in Argentina where among 100 000 maternity cases (as of 1945) the partial symphysiotomy of Zárate was employed in 0.22 per cent of patients. The author believes that this operation has a definite advantage over other procedures for the conditions narrated and that at one time it was employed in cases of infection in place of the classical section and the low cesarean section. With the advent of the antibiotics however these latter procedures proved more advantageous and have restricted the indications for symphysiotomy.

In the proper hands symphysiotomy has shown a low maternal mortality but a fetal mortality of 2.97 per cent from 1913 to 1931. In 1945 another series of 280 cases showed the maternal mortality was zero whereas the fetal mortality was 6 per cent.

STEPHEN A. ZIEKMAN M D

A Rare Indication for Cesarean Section: Thrombotic Varicosities in the Vagina KETJO SORVA. *Acta obst gyna scand.*, 1948, 28 77

Varicosities of the vagina and the portio of the uterus are relatively rare and are almost always associated with pregnancy. Such varices cause serious complications during pregnancy and delivery and the mortality rate had been estimated to be 60 per cent.

The author reports the case of a 31 year old bipara who was found to have extensive vaginal varicosities 2 weeks before her expected date of delivery. Varicosities were also present in both legs and the labia. Varices were palpable throughout the vagina, except for the portio. In addition, there was a protrusion through the vulva of a tumor composed of thrombotic varices about the size of an egg attached to the posterior vagina by a thick pedicle. Because of hemorrhage, the tumor was excised with considerable difficulty. Four days later a cesarean section was performed because of continued vaginal bleeding and the danger of obstetric trauma. Postoperatively thrombosis of the right leg occurred and heparin and dicumarol were administered. She was discharged 12 days after cesarean section without symptoms.

GEORGE BLUMICK, M D

NEWBORN

Obstetrical Shock and Pituitary Ischemia J F CUMMINGHAM. *Irish J M Sc.*, 1948, Ser 6 268

The author states that shock in an obstetrical patient is a dangerous complication which may be anticipated and frequently prevented. The cause of shock is hemorrhage trauma or both. The hemorrhage must be severe and rapid for slow chronic bleeding will not produce shock.

Trauma in the form of prolonged labor mismanagement of the third stage of labor or extensive lacerations of the genital tract may predispose to or produce shock. Most of these conditions can be anticipated and prevented by intelligent obstetrics.

With hemorrhage there is an equal loss of all the blood constituents. The tissues may be adequately oxygenated with only 25 per cent of the red cells but there must be sufficient plasma to circulate these cells. Shock may be prevented by immediate whole blood replacement or by intravenous glucose in saline or subcutaneous saline while the blood is being prepared. Further trauma or hemorrhage must be avoided. In patients with shock, there is a loss of plasma into the tissues with a subsequent concentration of the circulating cells. The hypotension found in shock further contributes to the inadequate circulation. If hemorrhage is also present the condition is even more serious. Fluids preferably blood or serum must be given immediately. Sedation heat and pressor agents are also helpful. Operation should be delayed until improvement appears.

Pituitary ischemia with subsequent necrosis may result from shock associated with parturition. If severe the necrosis may cause permanent invalidism or death. Early diagnosis may be lifesaving. The earliest symptoms are slow recovery mental confusion and lethargy hypotension and hypoglycemia. Anorexia results in hypoglycemia and coma, with or without convulsions. Pathological reflexes are usually present and lactation fails. The insulin sensitivity test is helpful in early diagnosis. In the later stages of this condition failure of pituitary hormone is evident.

Early treatment of pituitary necrosis consists of the prevention of hemorrhage and shock, good postpartum care and frequent observations of blood pressure blood sugar and mental status. Hypoglycemia if neglected for any period of time will cause death even though the blood sugar is restored to normal levels. 300 gm or more of glucose may be necessary daily. Adrenal cortex, adequate diet, and hydrochloric acid should also be given.

Anuria in Eclampsia (Anuria en la eclampsia. Su tratamiento eficaz por la novocaina intravenosa)
MAYNARD B. ROLLER LÓPEZ. *Obst. g. lat-amer* 91, 6, 44.

Ten cases of early post eclamptic anuria are reported in which treatment consisted in the intravenous administration of 10 c.c. of 1 per cent novocain. The results were excellent and the patients had in fact relief.

The author believes that eclampsia and anuria are the results of a vascular spasm in response to the internal secretions of the placenta. This transitory and paroxysmal gland suddenly incriminated in the hormonal constipation of the permanent glands to the secretions of which the patient is unable to adapt himself.

First hypotension and then anoxia develop from the embarrassed circulation which later affects all the organs of the body and leads to degeneration and necrobiosis. The anuria is only the expression of renal vascular spasm, at first functional and reversible but if allowed to continue it becomes irreversible and death may ensue.

Because of the premise that the condition is one of spasm, the treatment consisted of the application of a drug employed in other similar spasmodic conditions such as bronchial asthma, spasm of the retinal vessels (eclampsia amaurotica) and similar distal lancers. The administration of novocain should take

about 5 minutes and may be repeated in small doses every 6 hours.

Obstetrical Shock and Pituitary Ischemia J. CUNNINGHAM. *Irish J. M. Sc.* 1948, Ser. 6, 368

The author states that shock in an obstetrical patient is a dangerous complication which may be anticipated and frequently prevented. The cause of shock is hemorrhage trauma or both. The hemorrhage must be severe and rapid for slow chronic bleeding will not produce shock.

Trauma in the form of prolonged labor mismanagement of the third stage of labor or extensive lacerations of the genital tract may predispose to or produce shock. Most of these conditions can be anticipated and prevented by intelligent obstetrics.

With hemorrhage there is an equal loss of all the blood constituents. The tissues may be adequately oxygenated with only 25 per cent of the red cells but there must be sufficient plasma to circulate these cells. Shock may be prevented by immediate whole blood replacement or by intravenous glucose in saline or subcutaneous saline while the blood is being prepared. Further trauma or hemorrhage must be avoided. In patients with shock there is a loss of plasma into the circulating cells. The hypotension found in shock further contributes to the inadequate circulation. If hemorrhage is also present the condition is even more serious. Fluids preferably blood or serum must be given immediately. Sedation heat and pressor agents are also helpful. Operation should be delayed until improvement appears.

Pituitary ischemia with subsequent necrosis may result from shock associated with parturition. If severe the necrosis may cause permanent invalidism or death. Early diagnosis may be lifesaving. The earliest symptoms are slow recovery mental confusion and lethargy hypotension and hypoglycemia. Anorexia results in hypoglycemia and coma with or without convulsions. Pathological reflexes are usually present and lactation fails. The insulin sensitivity test is helpful in early diagnosis. In the later stages of this condition failure of pituitary hormone is evident.

Early treatment of pituitary necrosis consists of the prevention of hemorrhage and shock, good postpartum care and frequent observations of blood pressure blood sugar and mental status. Hypoglycemia, if neglected for any period of time will cause death even though the blood sugar is restored to normal levels 300 gm or more of glucose may be necessary daily. Adrenal cortex adequate diet and hydrochloric acid should also be given.

J. ROBERT WILLSON, M.D.

The Diagnosis of Postpartum Pituitary Necrosis. D. K. O'DONOVAN. *Irish J. M. Sc.*, 1948, Ser. 6, 364.

The diagnosis of postpartum pituitary necrosis during the puerperium is a difficult problem clinically and little aid is obtained from the laboratory. In suspected cases there is evidence from animal

work, that a therapeutic test with the use of 500 c.c. of cortical extract with glucose and saline during the first 24 hours, may be of value. Adrenocorticotrophic hormone may also be used but it has a latent period of at least 48 hours and is not a lifesaving procedure. The diagnosis in the later stages of the disease is even more difficult but the physician should remember that any patient with chronic symptoms, especially amenorrhea which dates from the last pregnancy is a possible case of pituitary necrosis. In such cases certain tests can be done to confirm the diagnosis. The basal metabolic rate is invariably below -15 per cent. If this cannot be performed it is fairly safe to rely upon a history of increased sensitivity to cold. The fasting blood sugar is usually low but it is also well to perform an insulin tolerance test according to the method of Fraser and Smith. The characteristic response in panhypopituitarism consists of a delayed return of the lowered blood sugar following insulin to the normal or pre-injection level. A positive response (insulin hypersensitivity) is probably due to a deficiency of the G hormone of the adrenal cortex as observed in Addison's disease. The effect also may be due to a loss of a hormone or hormones secreted by the pituitary which directly affect the metabolism of carbohydrate.

The urinary 17 ketosteroids are significantly depressed below 5 mgm. per 24 hours. This gives a clue to the degree of adrenal atrophy or to the amount of N hormone secreted by the adrenals. This test is of little value in mild or borderline cases furthermore it is not specific for pituitary necrosis.

All hypopituitarism is classified as primary or secondary. The primary group includes all of the organic lesions of the pituitary the secondary group is associated with any severe cachexia such as anorexia nervosa, and the author has postulated that such patients have a reflex inhibition in their pituitary hormones in reverse order of their importance a mechanism of importance in the biological adaptation to any chronic adversity. Menstruation is usually the first to be affected by inhibition of the gonadotrophic hormone. The secretion of the important life-maintaining N hormone of the adrenal cortex is the last to be affected and is never completely inhibited in secondary hypopituitarism.

From case histories and a review of the literature, it appears that in pituitary necrosis the surviving cells in the gland behave as they do in secondary hypopituitarism that is, they produce the more essential hormones at the expense of the biologically less essential ones.

In conclusion the author states that the diagnosis of partial pituitary necrosis is based mainly on an adequate history and little assistance is obtained from the laboratory. J. ROBERT WILLSON, M.D.

Postpartum Necrosis of the Anterior Pituitary II.
L. SHERMAN *Irish J. M. S.* 1948, Ser. 6, 341

Postpartum necrosis of the anterior pituitary is a relatively rare condition only 78 cases have been reported in the literature.

Necrosis occurs about 12 hours after delivery. Histologically the process cannot be recognized any earlier although the pathological process apparently occurs around the time of delivery.

The local cause of the necrosis of the gland is a thrombosis of parts of the vascular supply with a secondary ischemia. This local result is secondary to a generalized severe circulatory collapse as a result of hemorrhage shock, or both, at the time of delivery. The obstetrical complication must be severe enough to cause hemorrhage or shock but not severe enough to kill the patient for at least 12 hours after delivery. The most common obstetrical complication is postpartum hemorrhage and retained placenta. The obstetrical complication does not cause the necrosis, but it produces the circulatory collapse and/or shock, which in turn produces the necrosis.

Puerperal patients with large pituitary necroses have the following physiological disturbances the breasts do not become engorged with milk instead they are flaccid and devoid of secretion. The blood sugar is low usually in the range of 50 to 60 milligrams per cent. Polyuria is an inconstant finding. There is usually a loss of pubic hair.

Many patients with pituitary necrosis survive the puerperium, and the lesion becomes replaced with loose fibrous tissue. These patients, depending upon the size of the lesion are either relatively asymptomatic with only a slight delay in the return of menstruation, or they exhibit evidence of severe hypopituitarism.

At the Glasgow Royal Maternity Hospital, from 1935 to 1945, pituitary necroses were found in 15 per cent of the women who died in the puerperium later than 12 hours after delivery. Half of the necroses were large and the rest were moderate or small in size.

From these data, the author estimates that for each million of the population there were 5 large necroses in women who died in the puerperium. This evidence will probably decrease during the 1950's because of improved midwifery more adequate transfusion therapy and the use of penicillin and the sulfonamides.

The author estimates further that one in 3,500 adult women are suffering from severe chronic hypopituitarism and that their average life span after the necrosis is 15 years. He also states that along with better midwifery and the use of penicillin and the sulfonamides, more women will be saved and the total number of women suffering from chronic hypopituitarism will decrease.

J. ROBERT WILLSON, M.D.

The Neurologic Manifestations of Jaundice in the Newborn, with Particular Reference to the Chronic Residuals. LESTER B. MANN, JR., and CYRIL B. COURVILLE. *Bull. Los. A. Acad. Nat. Sci.* 1948, 131:69.

The effects of jaundice in the newborn on the central nervous system have long excited the interest of

the neurologists. It was noted early that these effects occurred mainly in cases of icterus gravis neonatorum but the exact significance of the cause of these effects was not recognized until the discovery of the role of the Rh factor in these cases.

It is in those instances in which the infant survives (as many will with more specific treatment) and in which we find the clinical manifestations of neuronal damage that the neurologist will be concerned particularly.

As listed by Zimmerman and Yannet the structures most commonly affected in order of severity are the subthalamic nuclei, the thalami, various nuclei of the cranial nerves, and in some instances the gray matter of the upper cervical cord.

The various theories regarding the actual cause of kernicterus are reviewed. None is satisfactory. However, the close association with erythroblastosis due to Rh incompatibility is now evident. Facts of interest concerning the disease are (1) that the nature of anti Rh antibody produced in the maternal circulation varies, i.e., it may be univalent or bivalent (2) that the Rh positive factor itself may vary as to composition (3) that cases of fetal erythroblastosis may occur which are apparently not caused by isoimmunization by the Rh factor (4) that the Rh group-specific substance is widely distributed in the tissues in varying amounts in different individuals, and yet in most cases may play little part in antigen-antibody reactions (5) that infants with erythroblastosis fetalis are particularly susceptible to asphyxia, presumably because of the reduced number of oxygen carriers (6) that a rise in titer of anti-Rh antibodies in the maternal serum may occur either early in pregnancy or not until the fetus nears term, but that the titer of anti Rh agglutinins in the blood of the mother may bear no direct relationship to the occurrence or severity of erythroblastosis in the infant (7) that in infants with kernicterus no uniformly marked anemia, icterus or other signs of blood destruction are found either clinically or at postmortem examination and (8) that icteric discoloration of the basal ganglia and gray matter has occurred without apparent premortem neurological manifestations.

It should be mentioned that cases of kernicterus have been reported which presented no evidence of erythroblastosis fetalis, icterus gravis neonatorum or even demonstrable Rh incompatibility.

The clinical manifestations of the acute phase of jaundice which may occur in the newborn with neurological symptoms are (1) the early appearance of jaundice, usually before the third day, increasing in intensity, (2) excessive somnolence and poor feeding (3) a high-pitched cry, (4) more or less intense muscular rigidity with opisthotonus, trismus, and spasms of the bulbar muscles (5) tonic and clonic convulsions, and (6) without treatment and in severe cases usually early death of the infant (during the first week).

It is in patients succumbing while icterus is present that the actual finding of nuclear staining is seen.

Of greater practical importance to the clinical neurologist are those cases of icterus gravis neonatorum in which the infant survives with evidence of chronic damage to the central nervous system. Parsons does not believe that the ultimate prognosis of icterus gravis neonatorum can ever be regarded lightly heartedly however successful its immediate treatment may be.

Sobel and Zucker have listed four late manifestations which they consider to be cardinal signs of the late syndrome of nuclear jaundice. These are (1) choreoathetosis (2) extrapyramidal spasticity (3) opisthotonus and (4) mental deficiency. They believe that the diagnosis of nuclear jaundice based purely on clinical grounds is justified if any three of these four signs are present with a history of severe jaundice at birth.

Various lesions have been reported. Two criteria must be met if one is to claim after pathological examination that a patient has survived an attack of nuclear jaundice following icterus gravis neonatorum. These criteria are as follows: (1) lesions should be limited to the striatopallidal portions of the brain which during the acute phase of the disease in the typical instance, are stained with bile pigments and show evidence of cell destruction (2) late lesions must be of a type which proves that a previous destruction of nerve elements in this system has taken place as demonstrated by (a) loss of nerve cells (b) demyelination, and (c) glial proliferation.

Studies into the possibility of Rh incompatibility as a factor in the production of feeble-mindedness have been undertaken by various groups of investigators. Klingman and Carlson reported their observations in a review of 675 cases of neuromuscular dysfunction. A history of severe jaundice was found in 45 instances. It was noted that the percentage of mental retardation and deficiency in these cases was extremely high.

Yannet and Lieberman reported the results in a group of children with IQ's below 30. These investigators found to cases (of 277) which might represent examples of cerebral damage due to maternal isoimmunization.

More recently Capell has written that he does not believe that Rh incompatibility as such has any relationship to mental deficiency except as it is the etiologic factor in icterus gravis neonatorum.

Parsons and Levine have separately stated their belief that if an infant with icterus gravis neonatorum (erythroblastosis fetalis) shows any neurological signs, no attempt should be made to treat the condition. Extensive transfusion therapy in such cases might merely substitute a living idiot for a dead baby, such therapy with Rh negative blood not being able to alter nerve cell damage that might have been occurring since early embryonic development.

The treatment of patients with chronic cases is largely a matter of symptomatic care together with rehabilitation measures designed to make the best use of remaining functions.

Why Is the Infant Born in Cephalic Presentation?
(Warum wird das Kind ans Kopfende geboren?) W.
WOLF, *Geburtsh. und Frauenk.*, 1947 7: 33.

The author discusses the different theories to explain why 97 per cent of all infants are born in cephalic presentation. The oldest is the gravity force theory which suggests that during the seventh and eighth months the head sinks toward the pelvis because of its greater specific weight. This theory was proposed first by Hippocrates and it prevailed until the beginning of this century. At that time extensive experiments with floating embryos disproved this possibility. X-ray and clinical examinations show that all embryos change their position freely and frequently until the first half of the ninth lunar month. After this time their position becomes gradually more stable until in the second half of the tenth month only 27 per cent of all embryos show a change of position. Two forces have been considered as the cause of the frequent changes of position: contractions of the uterus, and active movements of the embryo. The accommodation theory supposes that the adjustment of the embryo to the anatomic shape of the uterus results in cephalic presentation. This theory has been refuted by the fact that in cases of polyhydramnios, in which no adaptation to the shape of the uterus is possible, prevalence of cephalic presentation occurs in the same proportion as in normal pregnancies.

According to the author the main cause for the genesis of cephalic presentation is the spiral arrangement of the muscle fibers in the lower uterine segment, the cervix, and in the ligaments which run from the pelvic wall to the uterus and intertwine with the fibers of the cervix musculature. The action of these fibers is similar to the strings in an old-fashioned tobacco pouch or a coin purse. During the periodic

contractions of the uterus in the last period of pregnancy the lower uterine segment dilates, and the fetal head is caught by these fibers as in a trap. With each contraction the cervix descends, and the head is pulled down deeper into the small pelvis. The author devised a model to prove this mechanism. The cervix is represented by a rubber cuff. At its lower end strings are attached which represent the uterine ligaments. These strings are connected with metal rods opening the cuff in the manner of an umbrella. On pressure on a piston representing the fetal head, the cuff dilates and at the same time descends, and the piston is caught closely.

Studies on Insufficiencia Pelvis (Gravidarum et Puerperarum) SÖDER ÖRNELL. *Acta obs. gyn. scand.* 1948, 25.

On the basis of a large clinical material a syndrome is described for which the name "pelvic insufficiency" is suggested. Pelvic insufficiency is a condition that arises during the latter half of pregnancy and manifests itself in a deficient firmness of the pelvic joints (symphysis and sacroiliac joints).

Anatomical and radiological studies show that during pregnancy a loosening takes place in the pelvic joints which brings about an increase in the breadth of these joints. The consequent instability of the pelvis gives no subjective symptoms as a rule, but in certain cases (in close to 10 per cent in the author's clinic) this causes pathological muscular reactions and symptoms. The loosening of the pelvic joints takes place through the influence of estrogen and possibly the corpus luteum hormone (relaxin) as has been clearly proved in animal experiments.

The deficient firmness of the pelvic joints, as seen in the syndrome of pelvic insufficiency, causes pathological muscular reactions in the form of contractions, especially in the erectors dorsi. Objectively there are positive Lasègue and Trendelenburg signs on one or both sides as well as disturbances in gait; in extreme cases even waddling. Direct and indirect tenderness over the pelvic joints can often be registered. Subjectively the condition involves aches, pains, and difficulties in performing various movements involving the lower limbs: pelvis, and back. Pain associated with turning in bed, walking (especially up and down stairs) and on arising from deep chairs is common. Without treatment the condition may lead to invalidism. An effective therapy consists in measures to restore to the pelvis its stability and to counteract the origin of contractures. Calcium and vitamin D medication with some form of coarct treatment works in this direction. The results of this treatment are good.

The theoretical grounds on which pelvic insufficiency can be explained in certain cases of pregnancy are discussed. It is considered probable that in the background there is either a constitutional weakness in the pelvis and its supporting and motor apparatus, or an abnormally high increment from the placenta. It is also deemed probable that estrogen has a spe-

Fig. (Wolf) Arrangement of the cervix and ligament apparatus (after a drawing by Goertler). The ligament fibers are fixed to the pelvic wall at B, irradiate into the uterine wall, and embrace the lower uterine segment from both sides.

cific hyperemic action on the ligamentous apparatus of the pelvic joints and that future research should seek a closer explanation of the relationship between estrogen and calcium metabolism

GEORGE BLINICK, M D

Obstetrical Sequelae of Ligamentopexy by the Doléris-Pellanda Technique (Conséquences obstétricales des ligamentopexies suivant la technique de Doléris-Pellanda) J GOMOUT *Rev fr gyn obst* 1948 43 27

Since some obstetricians believe that ligamentopexy for uterine retrodeviations is responsible for later obstetrical complications the author presents a study of the future fertility of women having undergone this operation based on 290 postoperative pregnancies observed during the past 6 years

As regards the effect of ligamentopexy on fertility it was demonstrated that 10.4 per cent of women who were sterile before the operation became pregnant subsequently. The pregnancies following ligamentopexy were normal in 92 per cent of primiparas and in 93 per cent of multiparas. These figures indicate that the operation has no ill effect on pregnancy. Painful pregnancies were noted in 7.5 per cent of primiparas and in 6.5 per cent of multiparas. Threatened abortion occurred in only 5 cases and bleeding during pregnancy occurred in only 2 cases. There were 36 abortions. Urinary disturbances were rare. Presentation of the fetus was normal in 96 per cent of cases. The number of breech presentations was not greater than that observed in patients who had not undergone ligamentopexy. There were 6 cases of transverse presentation attributed to faulty technique. All 6 of the patients had been operated upon elsewhere. The incidence of premature delivery in primiparas subjected to ligamentopexy was 4.5 per cent, and in multiparas 5.1 per cent. The course of labor was normal. Forceps were employed in 4.5 per cent of primiparas and in 1.5 per cent of the multiparas. It is evident that the physiologic phenomena of labor are not adversely affected by ligamentopexy. Surgical intervention was required in only 3 cases. There was no maternal mortality and aside from the infant deaths which were due to premature delivery of nonviable infants the survival and health of the infants did not seem to be affected by the operation. The delivery and the immediate and late puerperal course were normal. Extrauterine pregnancy oc-

curred in 6 patients or 2 per cent of cases. Here ligamentopexy by the older technique might have played a part. It is only fair to state that some women who were operated upon for extrauterine pregnancy and subjected to ligamentopexy later experienced normal pregnancies

Ligamentopexy on a pregnant uterus is performed only in a very early pregnancy which was not recognized or in cases of incarceration of a retroverted pregnant uterus only 8 such cases were observed. These 8 cases included 2 patients with normal pregnancies who had normal deliveries at term 5 patients in whom the immediate results of pregnancy were normal and who were therefore not followed up and 1 patient who had had an abortion 2 months after the operation

As regards the late results of ligamentopexy some authors claim that recurrence is likely but the majority agree that retroversion does not recur even after repeated pregnancies

The author concludes that pregnancy is not affected by ligamentopexy if a proper technique is followed e g

The uterus must be fixed just sufficiently not too loosely or too rigidly. Also after anteversion of the uterus and verifying the state of the adnexa it is important that a thread be passed beneath the round ligament 3 cm. to 4 cm. from its uterine insertion in order to verify by traction upon it that the peritoneum about the round ligament is quite flexible and that the tube is not involved upon traction on the round ligament. The latter should exert a symmetrical traction leaving the uterus sufficiently mobile. Fixing the round ligament too close to its point of insertion would amount to a corporeal hysterectomy the obstetrical sequelae of which are too well known. Fixing the ligament at too great a distance from its point of insertion would favor a recurrence of the retroversion. The fixation should also be low. In this manner the round ligaments being drawn out side of the major recti muscles are brought into a normal anatomic position at the level of the internal inguinal orifice pulling the uterus forward. It is likewise important to avoid the famous death trap which may engage a loop of the intestine. On the whole it may be said that the ligamentopexy of Doléris-Pellanda yields excellent results and has no deleterious effects on subsequent pregnancies

EDITH SCHWARTZ MOORE.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Pheochromocytoma J A CAMPBELL COLSTON J
Urol. Balt., 1948, 59: 36.

The association of the clinical syndrome of paroxysmal hypertension with tumors arising from the medullary portion of the adrenal gland—pheochromocytoma or paraganglioma—has been recorded many times in the literature.

Pheochromocytomas are usually well encapsulated though the capsule may be thin and delicate. On section the tumor is soft and has a characteristic reddish brown appearance. The tumor cells are rather large and polygonal. The cytoplasm is coarse and granular and often contains basophilic and eosinophilic granules. The pheochrome properties of the cells are evidenced by their hazy, brown color. The nuclei are usually rounded or oval and most are hyperchromatic, some with large nucleoli. In general the tumor cells more closely resemble ganglion cells than the chromaffin cells of the normal adrenal medulla.

Attacks occur in which both the systolic and diastolic blood pressures rise within a few minutes from previously normal values to astonishingly high levels. The episodes last usually for 5 to 15 minutes and are often accompanied by nausea, vomiting and fainting spells with momentary unconsciousness. During the episode there is a feeling of marked anxiety and apprehension, and following it marked lassitude and complete exhaustion. Death may occur in one of the crises, either from acute myocardial failure or from a cerebral accident. The episodes may be brought on by lying in a certain position particularly on the side in which the tumor is located by straining at stool, and by emotional crises, such as anger or sudden fear.

When a patient presents the above syndrome the probability of the presence of a pheochromocytoma should be strongly suspected. Radiographic studies should then be carried out. In the flat film and intravenous urogram, a soft tissue shadow may be visualized in the adrenal area in some cases and the corresponding kidney may be displaced downward but in many cases, particularly when a small tumor is present, no significant information can be obtained.

The author believes that perirenal air insufflation although it is of great value in many cases, often yields equivocal results and sometimes carries great danger with it.

The intravenous injection of 0.05 mgm. of histamine as described by Roth and Kvale is a valuable tentative test for pheochromocytoma. The drug induces episodes which in all respects are identical with spontaneous attacks. An abrupt rise in blood pressure is produced which dwarfs that which accompanies the cold pressor test. The great value of the

test as a diagnostic procedure outweighs any possible dangers.

As soon as a tentative diagnosis of pheochromocytoma has been made surgical removal of the tumor is indicated to prevent the further occurrence of the crises, any one of which may end fatally.

The transverse abdominal incision gives excellent exposure and allows simultaneous exploration of both adrenals, but it carries with it a greater mortality and incidence of shock than the lumbar approach. The lumbar approach on the other hand is frequently accompanied by injury to the pleura. The author makes his incision over the tenth rib, starting posteriorly at the border of the erector spinae muscles, and carries it forward and downward. The eleventh and twelfth ribs are resected to give better exposure.

Care must be taken to avoid injury to the delicate capsule of the tumor. The blood supply of the tumor usually comes from the adrenal gland itself and hemostasis is accomplished by ligation of individual vessels. The adrenal gland often lies compressed upon the tumor and this makes it necessary to sacrifice the adrenal gland in order to effect complete removal of the tumor without tearing its capsule. As much of the adrenal as possible should, however, be spared because the adrenal on the opposite side may be absent.

The author reports 3 unusual cases of bilateral pheochromocytomas in blood relations. In one case a pheochromocytoma recurred because of incomplete removal. This was later excised. The hypertensive crises persisted however and a large tumor was subsequently extirpated from the opposite side with complete relief of symptoms.

In the second case, the patient's maternal aunt, hypertensive crises recurred 19 months after the removal of a pheochromocytoma. A large tumor was later removed successfully from the opposite side.

FREDERICK A. LAORO, M.D.

Management of Renal Trauma. J C KROGGER
and JOHN N. FURBER. *J. Urol.*, 1948, 59: 807.

Results of treatment in 7 cases of renal trauma are presented with detailed case reports of each patient. The patient with renal trauma may seem in excellent condition upon admission or may be in primary shock from which recovery is made in a few hours. Loss of blood may cause secondary shock a day or two later. Abdominal distention may occur but hematuria is practically always present. However the amount of bleeding does not necessarily correspond with the extent of damage. Pain is usually present. Increasing renal tubule function is caused by extravasated blood and urine and requires immediate surgery. Associated injury to abdominal viscera or the bladder may also be present. The diagnosis is based upon the history, clinical symp-

toms, and physical and roentgenographic findings. The excretory urogram is especially important diagnostically. Retrograde urography should be done if the urogram is unsatisfactory. Cystoscopy and ureteral catheterization may be safely done with proper technique.

Treatment may be surgical or conservative. Surgery should be done during the interval between primary and secondary shock. The good results obtained with conservative treatment of kidney wounds during the war were misleading because the wounds were usually open and draining. Observations of early results, complications and sequelae in many cases showed that the best results were obtained by early operation. No great harm is done by an occasional unnecessary operation but delay in adequate surgery is usually followed by serious results. Conservative treatment is frequently followed by serious complications.

Early operation is indicated when there is evidence of considerable loss of blood, secondary shock, massive hematuria, or increase in size of the renal tumor in cases of thoracic or abdominal injury requiring surgery when clinical or roentgenographic evidence indicates urinary extravasation from tears of the kidney or ureter when there is wide separation of renal segments or much displacement of the kidney or ureter and when the large renal vessels are torn. Infection, hydronephrosis, calculi and other complications are indications for late operations.

The injured kidney may be removed, repaired, or drained. Serious injury to the renal vessels requires nephrectomy. A torn capsule, pelvis or ureter may be repaired preferably early. Minor tears may be cured by drainage and packing. Conservative treatment consists of necessary sedation, general care and bed rest for 2 weeks or more. It may be satisfactory in tears of the capsule, ureter or pelvis without severe bleeding. Operation is indicated however if the blood loss is severe enough to require transfusion.

Nephrectomy was done in 4 of the reported cases. 1 patient was drained and 2 patients received conservative treatment. Operation was delayed to the fifth day in 1 case because of the patient's excellent condition. The roentgenogram showed widely separated segments and extravasation. Organized blood clots made repair impossible although this might have been done the first day after injury. Another patient was not operated upon for 12 days, but nephrectomy was finally performed because of continued blood loss and symptoms of infection. Neither delay was warranted. JOHN A. LOFF, M.D.

Wilms Tumor. WILLIAM J. DAW. *J. Urol.*, Balt. 1948, 60: 18.

Daw reports 7 cases of Wilms tumor. Three of the patients survived. He does not believe that radiotherapy alone will cure Wilms tumor. He elects immediate transperitoneal nephrectomy and postoperative irradiation. Early diagnosis is imperative. Prompt removal of the tumor by either immediate

transperitoneal nephrectomy or lumbar nephrectomy preceded by preoperative radiotherapy is necessary. There is no doubt that the efficacy of any operative procedure depends chiefly upon the presence of small and undiscovered metastases. There is some degree of difference of malignancy in the various Wilms tumors; some metastasize early, others late. Upon this factor depends the chance of survival of the patients who present themselves for operation. DAVID ROSENBLUM, M.D.

Osteogenic Sarcoma of Kidney. H. G. HAMEX and WILLIAM NILES WISHARD, JR. *J. Urol.* Balt. 60: 10.

The authors report a case of osteogenic sarcoma of the kidney and in a review of the literature on tumors of the kidney they discovered only 2 similar cases. Their patient was a 76 year old male admitted to the hospital because of frequency of urination and hematuria. A roentgenographic diagnosis of stomach ulcer had been made 4 years previously. Abdominal palpation demonstrated a tumor mass in the right upper abdomen. A benign hypertrophy of the prostate, grade 2, was present. Cystoscopy demonstrated median and lateral lobe prostatic hypertrophy and bloody residual urine from the right kidney pelvis. Roentgenograms showed an egg-shaped shadow in the region of the upper pole of the right kidney, displacement of the renal pelvis laterally and some dilatation. The presumptive diagnosis was hypernephroma with calcification. Irradiation was poorly tolerated and the patient gradually weakened and died. The immediate cause of death was hemorrhage from the bowel.

At autopsy the right kidney was found to be encased in a large amount of fat. At the lower pole of the kidney and slightly lateral to it was a tumor, 10 cm. in diameter, suggestive of lipoma. The remainder of the kidney contained a large, firm tumor mass which when incised contained a very hard mass which required incision with a saw and a chisel. The tumor arose from the supportive tissue posterior to the superior pole of the kidney and had grown into the kidney pelvis and inverted it without invasion. Some parts resembled normal red bone marrow and other parts consisted of hard, eburnated bone almost stony in consistency. Sections were typical of osteogenic sarcoma of the sclerosing type. Numerous areas in the lung contained definite bone formation and osteoid tissue the same as that present in the kidney tumor. In addition a large ulcer of the stomach, 4 cm. in diameter, was present, as well as smaller ones. The source of hemorrhage evidently was the stomach as the remainder of the gastrointestinal tract was normal.

DAVID ROSENBLUM, M.D.

Ureteral Ectopia. WILLIAM J. ENGEL. *J. Urol.*, Balt. 1948, 60: 46.

Engel reports the case of a male, 21 years of age, in whom a correct clinical diagnosis of ureteral ectopia opening into the seminal vesicle was made during a study on sterility. At no time had an emission of

semen ever been observed either at coitus or with nocturnal dreams. Physical examination was negative. Intravenous urography showed prompt right kidney function and no left side visualization. Cystoscopy with a panendoscope demonstrated that the left half of the trigone was thrown into rounded cystic elevations which covered the area normally occupied by the left ureteral orifice, with encroachment upon the bladder neck. Immediately proximal to the verumontanum and to the left of the midline was an irregular dark cavernous opening, and a ureteral catheter passed into it became coiled in a large lobulated cystic dilatation of the seminal vesicle. From the vesicle emerged a dilated ureter extending up to a hypoplastic kidney lying in normal position. Engel believes that the opening in the posterior urethra permitted semen to reflux into the cavity caused by the cyst of the vesicle and dilated ureter so no ejaculation externally ever took place.

The cystic left seminal vesicle was removed and a ureteronephrectomy was performed. This interesting anomaly is due to failure of the normal shifting of the terminal portion of the wolffian ducts and the ureteric bud. When this development remains faulty the ureter may be attached to the lower end of the wolffian duct, as a result of which the ureter may open into any organ or structure derived from the terminal portion of the duct. Thus, the opening may occur abnormally in the ductus deferens, seminal vesicle, ejaculatory duct, or posterior urethra. Associated developmental anomalies are frequently observed.

DAVID ROSENBLUM, M.D.

Retrocaval Ureter. C. D. CREEVY *J. Urol.* Balt. 94:5, 60: 26.

The author reports the case of a 12 year old girl in whom a retrocaval ureter was recognized preoperatively by the characteristic course of the ureter in the pyelogram. This is apparently the youngest patient subjected to a successful corrective operation the seventh patient in whom such an operation was successful and is the fourth case to be recognized by pyelography. The total of reported cases found by him now numbers 38.

The condition is an anomaly of the venous system in which the vena cava is formed from veins which lie anterior to the ureter in the embryo and which normally disappear early in the course of development. The ureter therefore passes behind the vena cava a short distance below the renal pelvis. In many cases no symptoms have been caused, but often the ureter is squeezed between the vena cava and the underlying tissues so that hydronephrosis develops.

The author's patient was studied because of recurrent pyelonephritis. The pyelogram demonstrated, on the right side, the typical deformity: the dilated lower pelvis and upper ureter formed a hook with its convexity downward and its pointed tip overlying the lateral margin of the spine, the ureter then arched medially and downward in front of the vertebrae to the level of the sacrum after which its contour and location were normal; the dilatation ter-

minated abruptly at the lateral margin of the spine where the ureter passed under the vena cava.

A right midclavicular transperitoneal incision was made, and the ureter was exposed and followed upward to its point of disappearance beneath the medial margin of the vena cava, where it was doubly ligated and divided. The distal portion was pushed laterally between the vena cava and posterior parietal peritoneum which then was sutured. The abdominal incision was closed, the patient was turned on her left side, and the right renal pelvis was exposed through a lumbar incision. The pelvis was freed together with the upper ligated ureter which was pulled out from behind the vena cava. The lower end was located and was approximated loosely to the upper end with a fine chromic catgut over a No. 14 Robinson catheter which was brought out through a stab in the renal pelvis. A pyelostomy was made with another Robinson catheter and both were brought out through the wound. The ureteral catheter was removed in 2 weeks, and the pyelostomy tube was removed 3 days later. The site of the anastomosis was frequently dilated for a period of 3 months after hospital dismissal, and the urine has remained clear and sterile.

DAVID ROSENBLUM, M.D.

Ureteropelvic Obstructions. ROY B. HICKLIN and CECIL J. HAWES. *J. Am. M. Ass.* 94:5, 37: 777.

In their explanation of the frequency of digestive disturbances in patients with renal disease, the authors emphasize the common nerve supply of the kidneys and intestinal tract. Negative findings in the urine and the absence of direct kidney symptoms do not rule out disease of the urinary tract. In ureteropelvic obstructions, malacating gastrointestinal symptoms are quite common.

With the advent of antibiotics, and recognition of the principles of treatment for partial obstruction at the ureteropelvic junction, the outlook for successful repair and conservation of renal tissue is improved. Nephrectomy should be less common.

The author summarizes his findings in 70 ureteropelvic obstructions in 52 patients who were treated during the period between 1942 and 1946. Operations were performed for 63 obstructions. Contrary to common belief extrinsic causes such as aberrant vessels, bands or adhesions are not the major factors in obstruction. In 71 per cent of cases the cause was intrinsic within the ureter with stricture and hypertrophy of the circular muscle which decreased the size of the ureteral lumen. In 3.9 per cent of cases the cause was extrinsic, and in 25.8 per cent the condition was due to combined causes.

In the preoperative study delineation of the ureteropelvic obstruction was made preferably by retrograde pyelography and a 1 minute delayed roentgenogram. In the operative procedure conformance to certain principles is more likely to insure success. The exact cause of the obstruction must be determined and it should be borne in mind that narrowing of the ureteral lumen is common and may exist even

if the ureter is normal in its outside appearance. The deformity must be adequately corrected and as a rule, the narrow ureteropelvic junction incised longitudinally. The authors have preferred the Y Foley plasty and they performed this type of repair in 45 of 63 cases. Nephrostomy drainage to divert the urine is necessary and a soft rubber catheter is inserted as a splint down the ureter about which the new widened ureter may mold. At this time pending experimental work to determine the process of ureteral healing both nephrostomy tube and catheter remain *in situ* for a period of 6 weeks.

In evaluating the success of treatment relief of symptoms alone is a false criterion. Such improvement may occur following denervation of the kidney especially around the ureteropelvic junction but progressive blockage and kidney destruction may continue. Improved renal function must be in evidence as well as improved drainage of the renal pelvis, as indicated by a retrograde pyelogram and delayed roentgenogram.

In this series, satisfactory results were obtained in 90 per cent of cases. This is a commendable figure and may be attributed to improved technique, a wise selection of cases, and a better means of controlling infection by the judicious employment of chemotherapy and antibiotics.

BLADDER, URETHRA AND PENIS

Pedunculated Bladder Tumors. E. GRANVILLE CRAWFORD. *J Urol* Balt. 1948 60 85

The author presents the remote end results in a series of 95 patients with pedunculated bladder tumors who were followed for long periods of time the majority over 7 years. The type of tumor was the pedunculated variety which remains sessile for a long time in many patients.

The treatment employed consisted of open supra pubic exposure of the bladder mucosa following which the tumor was grasped with a clamp and elevated so that other clamps could be placed below, until an apparently normal segment of tissue had been included. In some cases the entire thickness of the bladder wall was excised. Ties or sutures were used to effect the repair.

The majority of the patients treated were in the sixth and seventh decades. There was but one operative death in the entire series. Cystoscopic studies were carried out for the first 3 years and yearly thereafter.

Of 63 cases in which the author had obtained adequate data for conclusions 19 patients are well after an average period of 10 6 years. Extension of life beyond an average of 5 5 years occurred through re-exploration in 13 patients who eventually succumbed to death from tumors. Eight patients appeared to have had multiple carcinomatosis with a close relation in the appearance of the other cancers to the malignant exacerbation of the bladder tumors.

JOSEPH E. MAURER M D

Treatment of Bladder Tumors ARCHIE L. DEAN
J Urol Balt. 1948 60 93

The author states that the time has passed for advocating any single form of treatment for all bladder tumors because experience has shown that all accepted treatments have usefulness which varies in degree with different conditions in the bladder and urinary tract.

Transurethral electrocoagulation is sufficient to destroy single papillomas with bases no larger than 1 0 cm in diameter and multiple papillomas of the same size when there are no more than 15 in number.

Transurethral implantation of radon seeds with or without electrocoagulation has proved satisfactory for single papillomas or for papillary carcinomas larger than 1 cm. in diameter which are situated favorably as regards cystoscopic vision and are not too near the ureteral orifices or the vesical outlet.

Segmental resection of the bladder wall is an effective way of removing tumors of any grade of malignancy if the growth has not extended beyond the bladder wall and if the tumor can be removed with a safety zone of normal bladder wall, 1 5 cm. wide surrounding the growth. However experience has shown that segmental resection seldom removes all of the disease when the trigone is invaded by an infiltrating cancer.

Tumors between 1 5 cm. and 3 cm. in diameter either papillomas or carcinomas which are at least 1 5 cm. from the urethral orifice appear to be treated best by suprapubic cystotomy with implantation of radon seeds. If it is necessary to implant radon seeds nearer than 1 0 cm. to a ureteral orifice the ureter should be reimplanted in the bladder.

Ureterointestinal anastomosis with removal of the bladder and prostate is advocated for papillomatosis multiple papillary carcinomas and infiltrating carcinomas which are large or which invade the trigone prostate or ureteral orifice also for refractory recurrences after radon or segmental resection. This method of treatment is advocated occasionally when the bladder wall is extensively infiltrated and contracted. The ureters should not be dilated to a diameter greater than 1 5 cm. the bladder should be movable and there should be no more than moderate renal infection.

Cutaneous ureterostomy is followed by cystoprostatectomy for the same conditions as ureterointestinal anastomosis when the latter is technically impractical.

Roentgen therapy may cause significant temporary regression of a tumor but seldom cures and the treatment is exhausting and causes protracted cystitis and proctitis.

JOSEPH E. MAURER, M D

Total Cystectomy DEWARD O. FERRIS and JAMES T. PRIESTLEY. *J Urol* Balt. 1948 60 98.

Total cystectomy has gradually become recognized as an important form of treatment for certain patients who have vesical carcinoma. The main problems which have impeded acceptance of this operation are (1) the selection of patients (2) the operative

technique, (3) the operative mortality rate (4) post operative preservation of renal function and avoidance of significant renal infection, and (5) ultimate results which command respect. Each of these problems is discussed. Some have been fairly well solved and others await solution. In 219 cases in which total cystectomy was planned or accomplished between the years 1937 to 1946 inclusive, the hospital mortality rate was 13 per cent. For the last 5 years of this period the rate was 8 per cent.

Construction of Glandular Urethra in Hypospadias.

HARRETT BRENDLER. *J. Urol.*, Balt., 948, 59. 64.

During the past 30 years specific efforts at curing the glandular or balanitic variety of hypospadias have largely been abandoned because of frequent disintegration of the repair as well as the development of postoperative chordee and strictures involving the glandular portion. The problem in repair of the glans has been to find sufficient tissue to assure proper relaxation of the suture lines. With this in mind the author has devised a simple method to augment the amount of skin available for this purpose by modifying somewhat the first stage of the Thiersch Duplay operation.

The operation is performed in 3 stages separated by an interval of at least 6 months. The first procedure encompasses (1) release of the chordee with excision of all fibrous bands and (2) preparation of the glans for the second-stage operation. In correction of the chordee a transverse incision is most often used. Relief of the ventral curvature is based on the complete removal of fibrous tissue remnants. To aid in lengthening the penis, the hypospadiac meatus is often and proximally.

After the penis has been liberated from its ventral attachments it is dorsiflexed under moderate tension. A longitudinal midline incision is made on the ventral surface of the glans and deepened until it has attained the summit of the glans. The two halves are then spread apart bookwise and secured to the abdomen by means of mattress sutures of medium silk.

Closure is effected by conversion of the transverse incision into a longitudinal one using interrupted fine nylon sutures.

A snug gauze wrap-around is applied to the penis. The latter is maintained in dorsiflexion by a gauze bolster placed between it and the symphysis. The bolster also acts to control bleeding from the cut surfaces of the glans which is generally quite brisk. A dry occlusive dressing is applied.

Diversion of the urine by a bulbar urethrostomy or suprapubic cystostomy is performed only when indicated. Usually, however, an indwelling catheter introduced through the hypospadiac meatus, suffices.

The gauze wrap-around is removed after 4 or 5 days and the silk and nylon sutures in from 12 to 14 days.

After an interval of not less than 6 months the second stage of the operation is performed. A well defined gutter is present on the ventral aspect of the glans which is completely epithelialized. The repair

is executed along the classic lines of the Thiersch-Duplay method with slight modification. The parallel incisions are extended along the borders of the urethral furrow out to the end of the glans. The edges of the tube are approximated by a running subcuticular suture of fine chromic catgut, care being exercised to roll in the epithelial margins. Closure is effected by interrupted fine nylon sutures.

The results of this method have proved most satisfactory. Of 6 patients submitted to the complete procedure, a glandular urethra has been achieved in 5.
FREDERICK A. LLOYD, M.D.

Congenital Diverticulum of the Anterior Urethra (Divertículo congenito de la uretra anterior) RICHARDO ESCOBAR. *Rev. argent. urol.* 1947 6: 103.

A 16 year old boy had allegedly suffered from infancy with a peculiar condition of dysuria, being forced to adopt odd positions and contortions of the body in order to effectuate the prolonged act of micturition. The resultant stream was never full or normally powerful. A few months previously the patient had noted a small nodule located at the level of the perineum. Twenty days previously he became feverish and the dysuria was exaggerated, with intense burning, and pollakiuria every 30 or 45 minutes in turbid dribs and drops. Palpation disclosed a painful swelling the size of a large walnut, at the level of the root of the scrotum which became smaller with pressure. The excretory urogram was of no help, however, the roentgen urethrogram disclosed a walnut-sized diverticulum communicating with the bulbar portion of the urethra. The youth of the patient and the long history of urinary troubles led to its probable diagnosis of a congenital diverticulum, and following regression of the gross infective condition the sac was easily dissected out and the Van Gleason stain disclosed the presence of smooth muscle fibres in the otherwise densely elastic walls of the sac.

In the discussion, GONCOWITZ suggested further excretory urographic studies, despite the evidently congenital nature of the anomaly with search for disturbances of infective character in the higher reaches of the urinary tract, such as are common in affections of the neck of the bladder.

JOHN W. BRENNAN, M.D.

The Treatment of Stenosing and Inflammatory Fistulous Perineurthritis (Strictures with Fistula Formation) Sequelae of Acute Recurring Perineurthritis, by Urethrectomy and Extensive Perinectomy. (Traitement des périnéurites sténosantes et fistuleuses inflammatoires [dits récidivants avec fistules], Séquelles de Périnéurites aiguës récidivantes par uréthrectomie et périnéctomie.) L. SARAGHIEL. *J. urol. méd.*, Par 948, 54-3.

The author states that these lesions belong to the prehistoric surgical period. They are observed infrequently in European hospitals but are of frequent occurrence in Algeria. They are sequelae of maltreated or untreated, gonorrheal strictures, characterized by dysuria ranging from complete re-

tention to occasional urinary discomfort there is elephantiasis of the perineum from the scrotum to the anus, and the area is perforated like a sieve by multiple fistulas. The condition occurs in Moham medans between 30 and 80 years of age.

Anatomically there is involvement of the urethra and periurethral tissue. The urethra is strictured and it is impossible even after incision to introduce a probe still the urethra might remain patent for the passage of urine. The mucosa is irritated and proliferating and 6 to 8 cm might be involved. The periurethral tissue is sclerotic and the sclerosus invades the spongy body and the bulbocavernosus muscles and adheres tightly to the skin.

The extent of the lesion is determined by urethrography. This is done from the external meatus only or by a combination urethrography with injection of lipiodol from the external meatus and from a catheter which has been retrogradely introduced through a cystostomy. Lipiodol (40 per cent in gomenol) is used.

Conservative treatment of these lesions is believed to be of no help. The internal urethrotomy is not indicated because it does not treat the lesion as an entity. Cystostomy for diversion of the urinary stream is beneficial only as long as the catheter is in place and when the suprapubic drainage is discontinued the condition quickly recurs.

The operation of choice is urethrectomy and wide perinectomy. The author has practiced this operation for 4 years in approximately 400 cases. The procedure is a radical one which might deter the beginner by the large defect which results. It is performed as an en bloc procedure. Routinely a guiding rubber tube (French) 18 to 24 caliber is used to unite the urethral stumps. In cases in which suture of the urethra is impossible, the regenerative power of the urethral mucosa will bridge the defect. There was no fatality among the patients in the present series. With a few exceptions, re intervention was not necessary. During the postoperative period diathermy sounds were used.

A cystostomy was done routinely in the beginning however this is now reserved only for severe cases. If the perineum is only mildly involved and the urethrography does not reveal severe diffusion of contrast media periurethrally, no cystostomy is used. When the lesion is severe with multiple fistulas and the blood chemistry indicates kidney damage a cystostomy is indicated. The radical procedure is done after the acute inflammation has subsided and kidney function has returned to normal. Occasionally a perineal débridement is used.

Prior to operation, a catheter is introduced through the external meatus and another one retrogradely through the cystostomy. Whether or not the two catheters meet, a median incision from the scrotum to the preanal region is done. Electrocoagulation is applied for hemostasis and a square excision of the sclerotic block is attempted. The catheters must always be considered as the landmark for the longitudinal incision. If the catheters do not touch each

other this en bloc removal is done in stages always keeping contact with the catheters. After the healthy parts of the remaining urethra have been determined inflamed tissue must be removed towards the anus membranous urethra and scrotum. In cases in which the urethral mucosa is heaped up it ought to be resected. The scalpel is better than the electric knife because it permits differentiation between sclerotic and healthy tissue. The guiding tube is introduced its vesical end can be guided retrogradely into the bladder by means of the original catheter or by a curved hemostat, introduced either through the cystostomy or through the perineal end of the urethra. With the guiding tube in place the urethra is sutured in several layers. Where this is impossible mobilization of the adjacent tissue will help to cover the tube. Three layers are used. Primary closure of the skin is done with a wick but without a drain. Sulfonamides are applied locally and penicillin systemically.

The postoperative care must be meticulous. The length of the guiding tube permits its externalization in order to clean its intraurethral part daily. Ether and gomenol oil are used for cleansing and the guiding tube is then put back into place. The wick is removed on the third or fourth day. Separation of the wound occurs only rarely. The guiding tube must not be removed in cases of complete separation. After the wound has healed the guiding tube is replaced by a Nelaton or Marion catheter and the cystostomy is allowed to close. The catheters should be changed daily and urethral diathermy is indicated every other day. Bowel movement is prevented for 6 to 7 days after operation.

In the author's cases the results were good and normal micturition occurred. Urethrograms of 4 cases accompany the article.

In the discussion Pasteau expresses some doubt as to the permanency of cure because the patients have not been seen for check ups. The author considers that a complete cure has been obtained.

ERNEST BORS, M.D.

GENITAL ORGANS

The Morphogenesis of Prostatic Hypertrophy and Carcinoma and Its Clinical Significance (Die Morphogenese der Hypertrophie und des Karzinoms der Prostata und ihre Bedeutung für die Klinik) RUDOLF HOWALD *Helvet. chir. acta*, 1948, 15 Supp. 4

A histologic study of 300 prostate glands was carried out in order to investigate the morphogenesis and frequency of prostatic hypertrophy. The material consisted of glands obtained from specimens ranging from fetal life to senility. The author's study afforded the opportunity to observe certain features of the morphology of prostatic carcinoma and the relationship between adenomyoma and carcinoma.

The first changes of prostatic hypertrophy are observed sporadically at about the age of 45. Thereafter the degree and frequency increase proportionately with age so that in individuals over the age of

65 no prostatic gland is found free of hypertrophic changes. A distinction between the periurethral or inner gland from the prostate proper is rejected on morphologic grounds. The first evidence of growth appears in the connective tissue near the urethra where small spindle cell aggregates are found about the blood vessels. Soon the glandular alveoli in the vicinity come in contact with these aggregates so that small fibromas exist which in their further development, often become pure adenomas. Inflammatory changes in the initial stages of hypertrophy are never found. Potentially all prostatic gland tissue is capable of hypertrophy yet only in the central glandular portion are adenomatous nodules found. As a result of their pressure the peripheral glandular portions atrophy. After prostatectomy the previously compromised tissue of the peripheral portion undergoes development. Large pure fibromas develop with particular frequency in individuals above 70 years of age.

The actual cause of prostatic hypertrophy is still not clearly understood. None of the heretofore proposed theories is entirely satisfactory. A number of morphologic and clinical observations are in opposition to the view that a disturbance in hormonal equilibrium initiates prostatic hypertrophy.

Carcinoma of the prostate occurs with greater frequency than was formerly believed. Of rare occurrence under the age of 40 it appears with increasing frequency from age 45 on so that it is found in 40 per cent of all prostate glands in the age group over 70. The author's findings are in accord with Walther's, that in 30 per cent of all prostate glands from men over 40 a carcinoma is histologically demonstrable. Carcinoma always originates outside of adenomatous areas and is independent of these. There is no evidence that prostatic hypertrophy undergoes malignant degeneration. More than two-thirds of all carcinomas have their origin from the apex of the prostate for the most part dorsal to the urethra. Carcinoma develops independently of senile atrophy primarily in a region rich in stroma and scanty in glands. It often develops immediately adjacent to the capsule or to the septum between the lobes.

In histologic structure two types can be differentiated in the early stages the first being characterized by well pronounced alveoli which stand out much more prominently than normal gland tubules, while the second is characterized by narrow alveoli and solid strands of cells embedded in a rich stroma suggestive of a scirrhous tendency. Other cases develop as carcinoma simplex, and often different growth types appear in the same preparation. Carcinoma lying adjacent to the capsule has a pronounced tendency to break through the capsule into surrounding structures. Localized atypical epithelium in the prostate gland was formerly described, but at present an uninterrupted series of changes are recognized between the so-called atypical epithelium and infiltrating carcinoma so that all such changes must be considered as beginning carcinoma.

Since prostatectomy does not eradicate that region of the gland from which carcinoma most frequently originates it does not provide a better guarantee against the possibility of later development of carcinoma than partial electroresection. From this viewpoint there is scarcely any difference between different methods of prostatectomy. Only when carcinoma is recognized early can it be eradicated surgically with expectation of lasting cure. Therefore it is important to perform rectal examination on all men over 50. Prostatectomy for carcinoma must be carried out by the perineal or sacral route so that the posterior portion of the capsule can be removed. In the majority of cases which do not permit a safe radical operation a palliative electroresection offers as much as the more dangerous radical operation. The histologic examination of prostatic tissue obtained by electroresection or biopsy which reveals only adenomatous tissue, does not eliminate the possibility of carcinoma in the neighboring gland.

JOHN L. LINGGENT, M.D.

Causes of Death Following Transurethral Resection. WILLIAM L. McLAUGHLIN, JOHN P. BOWEN, and JOHN B. HOLYOKE. *J Urol* Balt., 1943, 39, 33.

In a review of 561 cases of transurethral prostate resection performed at the Mary Hitchcock Memorial Hospital from 1933 until May 31, 1947 it was found that 16 patients had died, a mortality rate of 2.9 per cent. The authors discussed the cause of death in these 16 cases, 13 of which came to autopsy.

51 deaths were due to septicemia, 4 to cardiovascular complications and 3 to oliguria syndrome. Death was due to hemorrhage and shock in 1 case, to agranulocytosis in 1 case and to necrosis of the adrenal gland in 1 case.

Each one of the patients having oliguria syndrome had excessive bleeding with prolonged attempts at hemostasis. Two of these patients had perforation of the vesicle neck, and 1 had the typical renal findings associated with lower nephron nephrosis.

The exact mechanism of the oliguria syndrome, although not entirely understood is considered by the authors to be due to tissue damage associated with hemolysis of red blood cells or destruction of periprostatic and perivesical tissues. These conditions lead to a specific renal response characterized by lowered urinary output and uremia.

The tissue damage is probably brought about by hypotonic irrigating solution (sterile tap water) which hemolyzes the blood as it enters the circulation by way of the prostatic veins or by injury to the periprostatic tissues when perforation occurs.

The oliguria syndrome can be prevented by the use of isotonic solutions. Irrigating media such as physiologic saline or 5 per cent dextrose solutions have definite limitations. In order to prevent excessive hemoglobinemia, the authors advise reduction of the height of the irrigating solution to the lowest possible effective level and avoidance of prolonged attempts at hemostasis when bleeding is excessive.

The authors include a brief clinical and pathological résumé of the cases of the 16 patients who died.

In summary the authors suggested that the technique of transurethral prostatic resection should be better understood and applied in order to reduce the mortality of this operation further.

The use of prophylactic antibiotics and chemotherapy before, during and after transurethral resection should materially reduce the incidence of death due to sepsis.

Fatal pulmonary accidents due to thrombosis of the leg veins could be reduced by early mobilization and the use of active leg exercises.

The use of isotonic irrigating solution or the judicious use of sterile water during transurethral prostatic resection should reduce the incidence of the oliguria syndrome.

CONRAD A. KUEHN, M.D.

The Distribution of the Testicular Artery (Internal Spermatic Artery) to the Human Testis. R. G. HARRISON and A. E. BARCLAY. *Brit J Urol* 1948 20: 57.

A detailed study of the vascular supply to the human testis is demonstrated by roentgenography and microarteriography after the injection of radiopaque media into cord vessels. The authors arrive at certain basic generalities regarding the vascular pattern of the testicular artery which are correlated with the mechanism of heat exchange in the testis and afford speculation on technical principles suitable for the preservation of arterial supply in orchiopepy.

The many discrepancies noted in the observations made by anatomists in the past beginning with the earliest description by Regnerus de Graaf in 1677 prompted this investigation. Fifteen fresh postmortem specimens of human testes from 9 individuals varying in age from 10 to 65 years were used. After a preliminary saline irrigation of the vascular system the specimens were injected either in a cord artery or vein as required with a radiopaque material. In most instances a 5 per cent colloidal bismuth solution with a few drops of wetting agent were used. Plain and stereoscopic lateral and anteroposterior roentgenograms of the gross specimens were taken. To visualize the finer details by microarteriography 3 mm. transverse sections were used.

The study showed generally that the testicular artery in its course down the cord first gives off branches to the cord itself then at an inconstant distance from the testis a variable number of arteries to the caput epididymis and the cauda epididymis. Descending further the artery may remain undivided or it may divide into as many as four branches at a variable distance from the ultimate destination at different points on the posterior border of the testis medial to the epididymis. Contrary to textbook teaching no main arterial branches pass in through the mediastinum. The artery single or divided passes obliquely through the thickness of the tunica albuginea to the underlying tunica vasculosa. Once in this area the vessels ramify over the surface of the testis in a variable pattern. The terminal branch

es converge in a centripetal manner along the septa toward the mediastinum, usually giving off secondary branches en route. The vessel may break up in to small twigs before reaching the mediastinum, or may bend back and form centrifugal vessels. Recurrent arteries are more numerous than those which pass straight to the mediastinum.

In the epididymis the caput is most favorably supplied with its branch or branches taking origin from the main stem as far as $3\frac{1}{2}$ inches from the upper testis. The arterial supply to the cauda may arise from divisions of the testicular artery or from the artery to the caput. The body of the epididymis receives the least direct contribution from the testicular artery.

In contrast to the arterial supply only a very small part of the venous drainage takes place through superficial vessels in the tunica albuginea. There are two groups of main venous tributaries in the substance of the testis. One group previously unobserved runs through approximately the middle of the testis connects with a vorticoso arrangement of small veins on the free surface of the testis, and acts as a short-circuiting anastomosis. The other deep veins converge toward the posterior border of the testis and drain only the parenchyma. All ultimately converge essentially to the region of the mediastinum to form a complex network of tortuous vessels which form the pampiniform plexus.

A suggestion is made that the details of the vascular pattern of the testis may be related to a mechanism for exchange of heat. The testicular artery lying in the midst of the profusely anastomosing pampiniform plexus may give up heat to these venous components. The arteries too run an extensive course on the surface of the testis before supplying the parenchyma and again heat may be given off. An issue of practical importance emerges from the superficial ramifications of the artery on the surface.

It is most desirable in performing orchiopepy to preserve the testicular blood vessels particularly for spermatogenesis. Yet, in the Torek operation the tunica albuginea is stitched to the fascia lata. If the testicular artery is undivided and lies on or close to the lateral surface of the testis, it is possible that such stitches may inadvertently ligate the only blood supply to the parenchyma through the vessel before the terminal branches which course inwards along the septa are given off. Such danger exists also in the operation for testicular fixation in torsion of the cord in which mattress sutures fix the tunica albuginea to the wall of the scrotum on the one hand and to the septum testis on the other.

MISCELLANEOUS

Dissolution of Urinary Calculi. LEWIS D. KEYSER, PHILIP C. SCHERER and LAWRENCE W. CLAFFEY. *J Urol* Balt., 1948 59: 826.

Practically all efforts to dissolve urinary calculi have been based upon the use of chemicals against

the crystalline part of the stone. The organic framework uniting the crystals has been ignored. In vitro studies were therefore made in attempts to develop an attack upon this organic framework. Urine is a supersaturated solution of numerous substances practically insoluble in water. Certain hydrotrophic compounds in urine make these substances soluble. One of these is urease, a hyperactive enzyme. These studies indicated that urease aids in dissolving calculi by permitting destruction of both their inorganic constituents and organic matrix. Papaya and trypsin were found less effective.

Attempts to dissolve calculi were made with ferments and G-strate solution administered by irrigation through ureteral catheters or nephrostomy tubes. The clinical application is described. The ferments used were 0.5 per cent urease, 0.5 per cent orthosyme, 10, and from 0.25 to 0.5 per cent ficin proteinase. These solutions were unsterilized. Case selection is important when attempting to dissolve calculi. Previously passed stones may be analyzed but attempts must otherwise be made to determine the nature of the calculus by the roentgenographic, urinary and blood findings. Oxalic and uratic calculi resist dissolution. The method of dissolution is not yet applicable to stones better removed surgically to those associated with a single kidney or to those associated with a hypofunctioning kidney on the opposite side. It is most useful for dissolving fragments left after operation or early calcareous recurrences. The patient must be intelligent, able to tolerate indwelling catheters and psychologically capable of staying in

bed and working with the apparatus for from 7 to 10 days. Sulfonamides or penicillin are used while the irrigation is in progress. The effort is stopped if roentgenograms do not show a definitely smaller stone after 10 to 14 days.

In these studies 0.5 per cent urease was the most effective stone solvent. Orthosyme, ficin proteinase and trypsin were comparable but less active. They act as digestants, partly dissolving the colloidal or organic matrix of the calculus and causing it to become so swollen that the crystalline matter is loosened and made more susceptible to dissolution by crystalline solvents. The action of G solution in vitro especially on alkaline calculi was intensified and accelerated by these enzymes. Irrigations with ferment-G solutions have been used in 18 cases of urinary calculi and alkaline-encrusted cystitis. Excellent results were obtained in cleaning up incrustations about suprapubic and nephrostomy tubes but several failures occurred with renal calculi. A stag-horn calculus in an infected kidney was materially diminished in size by using a nephrostomy above and a ureteral catheter below but nephrectomy was necessary because of increasing infection. The method was ineffective in a case of Proteus infection.

More clinical experience is required for proper evaluation of this procedure. The ideal stone solvent has not yet been discovered but is expected to be some diet, drug, or hormone which will be given orally or parenterally and which will secrete some stone solvent from the kidney.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Bone and Joint Changes in Hemophilia with Report of Cases of So-Called Hemophilic Pseudotumor RALPH K. GROOMLEY and REED S. CLEGG.
J Bone Surg 1948, 30-A 589

The authors report 6 cases of bone and joint changes in hemophilia and, on the basis of these cases thought it reasonable to conclude that in persons affected with this condition so-called hemophilic pseudotumors may arise first from hemorrhages originating in the joint and extending along the bone to produce pressure erosion second from subperiosteal hemorrhages which may at first lead to formation of new bone and later to the absorption and destruction of bone and third from cortical or medullary hemorrhage which may lead to cystic changes and later may destroy the bone or lead to fracture and further hemorrhage.

They considered it difficult in any one case to state accurately which route was followed. On the other hand it seems important to be able to recognize the condition early enough so that the destructive changes may be kept under control.

Osteoperiostitis Simulating Tumor. Some Remarks about Radiodiagnosis. Les ostéopériostites d'aspect tumoral. Quelques remarques sur le radiodiagnostic. F. BACLESSE, P. MALGRAS and G. GRICOUR.
Off J chir., Par 1948 64 249

The differential diagnosis between subacute or chronic osteoperiostitis and tumor of bone often presents a difficult problem to the clinician. The authors discuss 3 cases of osteoperiostitis in which the diagnosis was correctly made by roentgenography before biopsy was done. The condition cleared up under treatment with penicillin in all 3 patients.

The differentiation between inflammation and tumor are discussed and demonstrated in an instructive series of roentgenograms. Osteosarcoma usually involves the metaphysis only and stops at the epiphyseal line whereas in osteoperiostitis the lesions tend to spread toward the epiphysis and reach the articular surface. WERNER M. SOLMITS, M.D.

Two Cases of Melorheostosis (Deux cas de méloréostose) E. SORREL and L. QUÉNU. *Rev orthop* Par 1948 34 3.

Melorheostosis was described first by Léri, in 1929 as a not congenital hyperostosis involving the entire or almost entire length of the bones of one extremity either superior or inferior. The disturbance is very rare, only 40 cases having been published in the literature. In most cases the first symptoms were swelling of one finger or toe and limitation of movement in the adjacent joints. Very gradually in the course of years the hyperostosis spreads along all the bones

of the involved limb. In about half the cases on record signs of scleroderma were marked in the area of the hyperostosis.

The authors discuss 2 cases of melorheostosis beginning in early childhood and developing over a

Fig. 1 (Sorrel and Quénu). Left forearm: radius affected in its whole length, with little involvement of elbow; however the superior apophysis is spotty and insertion of the anterior brachial muscle seems opaque. Lower end of the humerus is affected in its lateral half.

Fig. 2. Left humerus. Irregular densities of the lateral corticalis. Spots at the superior end of the humerus.

period of years. Signs of scleroderma in the affected areas were observed in both cases. In contrast to the classical picture both cases involved more than one limb. In one case both arms were affected in the other roentgenograms revealed that the bone lesions were multiple and widely scattered, with involvement of the left arm, the pelvis, both tibiae, femurs and the right metatarsus.

The etiology and pathogenesis of the condition are unknown. Many hypotheses have been presented. In view of biopsy findings and of the coincidence of this bone dystrophy with skin and connective tissue disturbances, the authors suggest that melorheostosis may be closely related to neurofibromatosis.

WERNER M. SOLMITZ, M.D.

Localized Osseous Lipoidosis (Lipoidosis osseae localis) C. CASUCCIO and G. GHERLINSONI. *Chir. org. intern.* 94B, 32, 7.

A 53 year old woman had suffered attacks of pain in the right hip for 15 years. Two years previously tumefaction of the right hip region was noted. A month previously the pains became severe and continuous, and began radiating along the course of the sciatic nerve. Roentgen examination disclosed large roundish, clear-cut shadow defects resembling cystic formations with sharply defined, dense borders. These shadow dehiscences occupied the neck of the femur, the epiphysis, the floor of the hip joint socket and even extended over into the neighboring osseous substance of the pelvic bone. The lower arched portion of the femoral neck leading down to the diaphysis exhibited the normal trabecular structure of nor-

mal bone. Some of the shadow defects were confluent, while others were separated by more or less delicate septal structures. The areas of deossification at no place encroached upon the heavy cortex of the femoral diaphysis. It is this roentgen picture which led the authors to suggest that the roentgen findings might be sufficiently characteristic to be of differential diagnostic value (Fig. 1) especially in distinguishing this localized condition from Recklinghausen's osteitis fibrosa with which condition it is most often confused.

Operation which included a disarticulation of the hip joint, uncovered the yellowish-orange colored masses characteristic of the lipoid tumor in which the type of lipoid present is cholesterol (Hand-Schödlér-Christian disease). Some of the masses were removed and an arthrodesis was done with the use of the greater trochanter as a transplant. Two months later the transplant was found to have healed in well the patient had not suffered any further pain or other discomfort and the appearance indicated that considerable reossification had taken place in the lacunar areas (Fig. 2).

Histologic examination of the excised specimens showed the typical picture of lipoidosis with the nests and infiltrations of the spumous cells interspersed among the masses of cells with the same general

Fig. (Casuccio and Gherlinsoni)

Fig. 2. (Casuccio and Gherlinsoni)

characteristics but without the eccentric nuclei: copious cellular protoplasm and foamy appearance of the true spumous cells. The peripheral areas indicated a more active, hypervascular condition than the more storage-cell like appearing central areas. Papanicolaou silver impregnation stain indicated a heavier than normal contingent of collagenous fibrils. These fibrils were arranged in a closely felted rete and were often irregularly dilated into a bulbous appearance or were tortuous in course. This appearance was repeated in many of the haversian lacunae of the neighboring bony tissue and there was no evidence of a well developed capsule between bone and tumor masses. In fact, the whole picture indicated that the process had originated in the endothelioreticular tissues of the haversian canals.

The patient died of an intercurrent malady before the authors were able to establish the character of the lipid present as cholesterolin however they believe that the nature of the fatty substance concerned was sufficiently established and if this is so this seems to be the thirty fourth instance of the localized form of Hand Schueller-Christian disease to be reported in the medical literature.

JOHN W. BRENNAN, M.D.

Neuralgic Amyotrophy The Shoulder Girdle Syndrome. M. J. PARSONAGE and J. W. ALDEN. *TURNER, Lancet* Lond. 1948 1 973

The authors present a group of 136 cases of a syndrome consisting of pain and flaccid paralysis in the shoulder girdle muscles without constitutional symptoms. These cases were observed during the period from 1941 to 1945 in the British Army at home and in India.

The clinical picture is one of sudden acute pain across one or both shoulder blades which may radiate into the neck or arm. After a period varying from hours to days the pain is replaced by atrophy and flaccid paralysis of one or more muscles. There are many modifications of the clinical picture of the syndrome as a review of literature on the subject shows.

This group of cases was carefully analyzed from every angle and it is significant that 66 of the 136 patients were hospitalized for some other condition when the syndrome began. In 98 of the cases a possible precipitating cause was evident. In 71 patients the syndrome started during convalescence from an infectious process as malaria or minor fevers. In 12 following simple surgery performed from 3 to 14 days previously. Minor trauma to various parts of the body occurred prior to the syndrome in 10 cases and various diagnostic procedures had been done previously in 5 cases. Only 67 of the patients were questioned concerning recent inoculations, and only 11 had such inoculations within the previous 4 weeks. One case developed in a man within 2 hours following the intravenous administration of typhoid vaccine to produce protein shock.

Fever and constitutional symptoms were notably absent and although local pain was the striking

symptom in most cases 2 men developed weakness and atrophy without pain. The pain usually decreased or left when weakness appeared. The location of the paralysis could not be forecast from the distribution of pain. Weakness was usually maximal at the onset but in a few cases progressed over a period of from 2 to 7 days.

The type of involvement suggests that the pathologic process may include not only one or more peripheral nerves but the spinal roots and even the spinal cord. The serratus magnus is the muscle most commonly involved either alone or in combination with the deltoid, spinati or thumb and index finger flexors. In 58 cases there were objective sensory changes on examination, which were usually slight and included all forms of cutaneous sensibility. There were 39 cases in which both sides were affected occasionally with an interval between onset of the paralysis on the second side.

No specific treatment is known and these cases were managed much as cases of poliomyelitis. The prognosis is based on the same principles as that in poliomyelitis.

The etiology is unknown. Absence of constitutional symptoms lessens the likelihood of the conditions being a virus infection. The condition is very similar to that known to complicate the injection of serum occasionally.

The authors suggest the name 'neuralgic amyotrophy' as most accurate in the light of present knowledge of the condition.

FRANCES E. BRENNICEK, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS ETC

Reconstruction of the Elbow Joint EDWARD PARSONAGE. *J Bone Surg* 1948 30-A 753

After discussing the various methods of reconstruction of the elbow and their disadvantages the author presents a revised medial approach for this procedure.

A semicircular incision 5 inches long is made over the medial aspect of the elbow. The ulnar nerve is identified freed from its bed and retracted with tape. The medial epicondyle is osteotomized and discarded. All soft tissues about the lower end of the humerus and including the humeroulnar ligaments are cut by sharp dissection to enable complete exposure of the joint. At the completion of the skeletal repair the ulnar nerve is transposed anteriorly and subcutaneously the muscles are approximated and the wound is closed. A hanging cast may be applied for one week.

Even patients have been operated upon by this method. Six patients sustained severe fractures caused by missiles. One developed suppurative arthritis following a simple fracture of the lower end of the humerus.

The postoperative results are classed as firm ankylosis in 6 cases, and unstable elbow joint in 1 case. SAMUEL L. GORRAN, M.D.

Coracoclavicular Joint. Surgical Treatment of a Painful Syndrome Caused by an Anomalous Joint. LUIS GUSTAVO WERTHMEYER. *J Bone Surg* 1948 30-A 570.

Proved cases of an anomalous joint between the coracoid process of the scapula and the clavicle have been reported 50 times. Often the condition has existed but has not caused symptoms. Osteoarthritis was demonstrated in a painful case which improved after resection of this joint. Apparently trauma or arthritis cause the joint to be a source of pain.

The author describes a patient who 3 years before had strained his shoulder. He developed pain in the shoulder which radiated to the arm. He had been unable to work for 2 years. There was limitation of abduction flexion and external rotation, and these motions were painful. There was tenderness in the deltoid area. Conservative treatment gave no relief and no pathology other than that the coracoclavicular joint could be demonstrated.

After resection of this joint, painless normal function was established. NEWTON C. MEAD, M.D.

Internal Fixation for Lumbosacral Fusion. DON KIRK. *J Bone Surg* 1948 30-A 560.

The lumbosacral fusion described in this article is performed after subperiosteal exposure of the spinous processes, the laminae and the articular facets of the vertebrae to be fused. The facets are exposed easily by the use of a Bennett retractor with a notched tip. The tip is placed against the lateral mass of the first sacral vertebra and the soft tissues are pried laterally. The articular surfaces are removed with a special osteotome which is curved to fit the curve of these joints. The spinous process of the fifth lumbar vertebra is removed. A No. 31 drill is used to make a hole downward and outward parallel with the inferior border of the lamina at an angle of 45 degrees. This crosses the articulation and is a tunnel for the screw. A 1 inch screw is used in male patients and a 3/4 inch for females.

Numerous small grafts are elevated from the fifth lumbar laminae and the sacrum and grafts from the ilium are arranged against the raw surfaces. Sometimes a tibial graft is fastened by means of screws to the remains of the spinous processes of the vertebrae and sacrum.

There have been 2 wound infections requiring removal of the screws, and in 1 case a screw caused nerve root irritation. There were no deaths in the series reported. Definite pseudarthrosis developed in 9.1 per cent of the cases, but the clinical results were about as good in these as in those of patients who obtained solid fusion.

Based on his conclusions on 44 patients who were operated upon during the years from 1940 to 1945 the author believes this method of fusion is superior to methods which do not firmly fix the position and relationship of the bones at the time of operation. There is no need for prolonged immobilization in plaster postoperatively and the patients are comfortable. NEWTON C. MEAD, M.D.

Radical Operative Treatment of the Tuberculous Hip. A Report of 113 Cases. ALBERT AMARZ. *J Bone Surg* 1948 30-A 550.

This report is based upon end-result studies of 113 proved tuberculous hips operated upon during the years from 1929 through 1944. These supposedly treated hips represent 15.6 per cent of a total of 479 tuberculous hips treated during that period.

The operation is done through a superior-anterior approach, but the psoeum is not stripped from the ilium because it is believed that the circulation of this bone should not be impaired. The hip is dislocated and all capsular tissue is excised. Sinus and abscesses are excised if possible and curetted to healthy bone. No grossly diseased tissue is left. The raw surfaces are then cauterized with phenol and alcohol, the femoral head is placed in the acetabulum and the wound is closed.

If destruction of the head and neck of the femur is massive the trochanter is transplanted into the acetabulum. Sometimes extra-articular fusion is done in conjunction with resection. Eleven such cases are reported.

Operative findings included 63 abscesses, 50 acetabular sequestra, and 26 sequestra in the femoral head and neck. The process had perforated from the acetabulum into the pelvis 34 times, and the capsule was found grossly thickened in nearly all cases. In none of the cases was it found necessary to give blood transfusions postoperatively.

Primary healing occurred in 64 of the patients and 22 developed well established fistulas. There were 5 deaths occurring within a short time of the surgery.

The postoperative care averaged about 6 months. The patients were kept in bed in plaster for 3 months, but motion of the knee was permitted after 4 weeks. After a period of 3 months a short (knee length) unilateral hip spica was applied and crutch walking was begun.

It is interesting to note that only 8 of the patients had bony ankylosis at the time of discharge, but they were all bearing weight and walking. In a late follow-up 58 of the hips were found to have fused. It should be mentioned that in the early years of the series early motion was permitted because bony ankylosis was not desired by the surgeon at that time.

Another cause of failure of fusion was the necessity of removing large amounts of bone and in some cases the disease continued to destroy bone. An extra-articular fusion can be done later if fusion is considered necessary. Some patients developed painless motion and fairly good function, but it appears that the author favors fusion as being the best result obtainable after this surgery.

The author's indications for resection of the joint in tuberculosis of the hip are

1. Abscess formation.
2. When fistula formation appears imminent.
3. The formation of sequestra.
4. A tendency toward subluxation or dislocation.
5. The patient should be 16 years of age or older.

NEWTON C. MEAD, M.D.

FRACTURES AND DISLOCATIONS

Fracture-Dislocation of the Hip Joint. The Nature of the Traumatic Lesion Treatment, Late Complications, and End Results. MARSHALL R. URIST *J Bone Surg* 1948, 30-A 699.

The author reports on 27 cases of dislocation of the hip associated with major fractures of the acetabulum or head of the femur with 2 year follow up studies. In 15 cases open reduction was performed and the nature of the injury surveyed.

Injury to the rim of the acetabulum inflicted by a sudden impact of the dashboard against the flexed knee constituted the first stage of a fracture-dislocation. The damage to the posterior rim varied in magnitude from insignificant bruises or chip fractures to fractures of great segments of the entire posterior and superior portions of the acetabulum. Less than half the head of the femur lies outside the bony acetabulum in the normal hip so after many of the supporting structures in the capsule have been ruptured the integrity of the posterior and superior portions of the rim appear to be of increased importance to the stability of the hip.

The major damage to the soft parts of the joint was usually sustained by the parietal or external portion of the capsule rather than the visceral or reflected part which carries the major portion of the blood supply to the head of the femur. When a large segment of bone was detached from the rim the capsule was essentially intact except for a single tear in the posterior portion. The short external rotators however, sustained considerable damage. The belly and tendon of the piriformis were stretched over the head of the femur. The tendon of the obturator internus was stretched over the neck. The gemelli were torn and shredded. All of these structures were infiltrated with blood and matted together with fibrinous exudate and granulation tissue dissection was difficult if operation was done longer than 2 weeks after injury.

Almost every case showed some damage to the articular surface of the head of the femur but these lesions were small and not visible roentgenographically. Even fractures of some magnitude could not be demonstrated in anteroposterior views alone, or in films made by routine or imperfect techniques.

In 3 cases in which the posterior portion of the acetabulum had been removed the ligamentum teres was found to be stretched and frayed. Complete visualization was possible in only 2 cases in which the hip had been disarticulated and in both instances the ligamentum teres had been severed. It is possible that in one case it was stretched and not torn apart, and that in many cases the excursion of the head was not so great as appeared in the roentgenograms.

Blood clot and organizing hemorrhage were seen in the retinacula in 2 cases. One year later only these 2 cases showed disintegration of the bone structure of the superior portion of the head of the femur. The retinacula serve as aqueducts carrying blood to the

head of the femur. They are little mentioned in the literature but are important and their role in avascular necrosis demands further study in relation to both trauma and disease of the head of the femur.

In 15 cases of fracture of the rim of the acetabulum with dislocation the dislocation was reduced by closed manipulation just as readily as were the dislocations without fractures treated earlier by the author. In about 25 per cent of the cases the diagnosis of fracture was not recorded by the surgeon who first treated and manipulated the dislocation. The fracture is best seen in a postero-oblique view with the injured side elevated 60 degrees the patient lying supine on the cassette which places the posterior portion of the acetabulum in profile. Ten of these patients were treated by closed reduction of the dislocation followed by arthrotomy. The decision between replacement and fixation of the fracture or the removal of the fragments was made at operation and depended upon the presumed vitality of the bone fragments. The operation itself was always indicated when there were loose fragments around the joint which might lead to migration of intra-articular bone ossification of periarthritic structures irritation of the sciatic nerve, or the probability of a painful joint in later years. The technique of operation is described in detail.

There were 8 cases of fracture of the acetabulum with posterior dislocation irreducible by closed manipulation. This was due to interference by displaced bone fragments. Conservative treatment in traction was of limited value in these cases but it was essential for the patient's comfort and it was necessary temporarily to retain anatomical approximation of the head of the femur and the fractured pelvis.

In 4 cases there were gross fractures of the head of the femur associated with dislocation of the hip. Three patients were treated conservatively. One patient showed appreciable limitation of motion of the joint under anesthesia after the dislocation had been reduced therefore an arthroplasty was performed.

The early complications encountered in this series of cases were retroperitoneal hemorrhage injuries of the urinary tract thrombosis of the hemorrhoidal veins thrombophlebitis sciatic neuritis and palsy of the sciatic nerve. Late complications included ossification of the joint capsule synovitis, avascular necrosis of the femoral head, and traumatic arthritis.

The 2 year end results are given in detail. The author concludes:

1. Fractures of the posterosuperior rim of the acetabulum with displacement should be repaired as carefully as any other fracture of a weight-bearing joint.

2. Fractures of the posterior rim of the acetabulum associated with dislocation of the hip should be treated by cautious closed manipulation followed by open reduction and internal fixation of the fracture through a posterior approach.

3. Dislocation of the hip joint associated with comminuted fracture of the acetabulum should not be subjected to closed manipulation.

4 Fractures of the head of the femur except in cases in which it is necessary to reduce the size of the head or to excise the intra-articular fragments are best treated by conservative methods.

5 Degenerative arthritis may be expected to occur in most cases in which the superior or weight-bearing surface of the head or the superior rim of the acetabulum is defective and in many cases in which fragments of cartilage and bone are not cleaned out of the joint by operation.

J M J CRANE JR MD

ORTHOPEDICS IN GENERAL

An Evaluation of Penicillin Therapy in Acute Hematogenous Osteomyelitis. W A ALTMAYER and C L WADSWORTH. *J Bone Surg* 94B 30-1 1957

The efficacy of penicillin therapy has been studied among 71 cases of hematogenous osteomyelitis during the last 4 years. Six hips, 6 knees and 1 ankle joint became secondarily infected by contiguity. Sixty three or 90 per cent of the patient were 30 years old or less. Fifty five (77%) of the patient were males and 16 were females. The point of frequency of portals of entry of the hematogenous infection were furuncles, infected cutaneous abscesses, upper respiratory infections, suppurative otitis media, infected teeth, gingivitis, parotitis, chicken pox and scarlet fever.

In 70 per cent of the cases the offending organism was the hemolytic *Staphylococcus aureus*.

While the usual dose of sodium penicillin was between 15,000 and 25,000 units. Later in the study a high as 100,000 units were given either parenterally or intramuscularly every 2 to 3 hours. The results were extremely satisfactory. All of the patients recovered with the exception of one. This patient entered the authors' service in a moribund state suffering from an acute hematogenous osteomyelitis of the tibia with staphylococcal bacteremia, and died 17 hours after admission. Obviously the results vary with the severity of the infection, the dosage of the penicillin, and the commencement of treatment. Excellent results were obtained in patients in whom the diagnosis was made and penicillin therapy administered within 6 days of the onset of the disease. Poorer results were noted in cases in which the treatment was not instituted until 7 days or more after the onset of the disease. To enhance the excellent recoveries of hematogenous osteomyelitis the authors have observed the necessity of immobilization, prevention of weight bearing and latent or delayed surgical drainage of large osteomyelitic abscesses.

Nine recurrences have been noted in 67 follow-up cases. The majority of the recurrences are attributed to insufficient treatment. Larger doses of penicillin decrease the morbidity and duration of the stay in the hospital and augment the therapeutic efficacy.

The authors have pointed out that since the hemolytic *Staphylococcus hemolyticus*, *Streptococcus*,

nonhemolytic *Streptococcus*, and *Pneumococcus* are extremely sensitive to penicillin early administration should prevent the extensive thrombosis of the nutrient vessels with periosteal stripping, and lower the previous mortality of 25 per cent to a new low of 1.4 per cent as attained in their series. To avert serious complications the surgeon or the family doctor must make the diagnosis early and on the basis of the clinical manifestations of osteomyelitis. Delay of from 10 to 14 days to await roentgenological evidence of bony lesions invites irreversible pathologic changes.

Early decompression of infected bone was not practiced in this series. Adequate and early administration of penicillin obviates the necessity of surgical intervention in osteomyelitis. Sequelae were observed in 6 cases only.

S MUEL L. GOWERALE, MD

Functional Substitution in Irreparable Radial Nerve Paralysis (Der funktionelle Ersatz bei der irreparablen Radialislähmung) ALFRED NIKOLAUS. *W W Chirurg* 94B 9 1957

The author discusses his experience with the surgical treatment of 260 patients with radial nerve paralysis. There were 125 treated according to the classical Perthes procedure and 135 treated by an extensor tendon plastic procedure which consisted of transplantation of the flexor carpi ulnaris and radialis muscles without tenodesis. The simplified Perthes plastic procedure of Bauer was also taken into consideration.

The classical Perthes procedure consists of tenodesis (1) tenodesis of the extensors carpi radialis brevis and longus through a canal in the radius, and subperiosteal fixation of the extensor carpi ulnaris to the ulna, and (2) transplantation of the flexor carpi radialis and ulnaris and the palmaris longus to the extensor tendons.

The extensor tendon plastic procedure avoids fixation of the wrist by tenodesis and depends upon dorsal transplantation of the flexor carpi radialis and ulnaris. In the event that the palmaris longus is well developed it may be used in place of the flexor carpi radialis.

Bauer operation consists of dorsal transplantation of the flexor carpi ulnaris and suture to the distal ends of the sectioned extensor digitorum communis tendon in order to obtain extension and suture of the proximal ends of the sectioned extensor tendons to the dorsal carpal ligament in order to eliminate wrist drop by a braking action. The author has used this method in a few cases.

A consideration of the comparative value of the three procedures cannot be based on technical simplicity, but rather must depend upon a critical evaluation of late results. The author believes that when certain prerequisites are fulfilled the classical Perthes procedure is the best method. By tenodesis the greatest danger, namely overstretching of the transplanted muscles, is eliminated. The objection that tenodesis causes a loss of wrist flexion is correct.

but this is compensated for by greater mobility and play in finger movements which results from the fact that a part of the muscle power is not used to fix the wrist. The amount of dorsiflexion procured by tenodesis can be adapted to the needs of the individual patient. Dorsal fixation of the wrist by tenodesis provides the three wrist flexors for transplantation which appears to be of greater value than transplantation of one or two flexors, especially with respect to thumb extension and abduction.

Contraindications for tenodesis are (1) the presence of marked limitation of movement at the shoulder or elbow because a slight amount of wrist motion is of the greatest importance in these cases (2) contracture or ankylosis of the wrist joint to the extent that a frank wrist drop is not present (3) the expressed wish of the patient not to have the wrist fixed and (4) occupations which require predominating function of the wrist in flexion.

The extensor tendon plastic procedure is a good one under sharply circumscribed indications. It is performed when one of the contraindications to tenodesis is present and is the procedure of choice in partial radial nerve paralysis when wrist extensor function is preserved. In a few selected cases in which strong wrist flexors are present, tenodesis can also be dispensed with. The deficiencies of the extensor tendon plastic operation for other cases result from a division of the power of the transplanted muscles between maintaining wrist extension and providing finger function which is detrimental to the latter. Further the position of the wrist may gradually return toward flexion so that the power of grip is lost. The differentiated movements of the fingers cannot in most cases compare with those obtained by the Perthes classic operation, and the function of the thumb cannot be restored as favorably because the palmaris longus is not used for the isolated substitution of the extensor pollicis longus. In hard working men the substituted muscles are liable to overstretch in the absence of tenodesis. In spite of these deficiencies the extensor tendon plastic operation often shows astonishingly good early results but as time goes on it brings disappointment unless strict indications are observed.

The author objects to Bauer's operation on the following grounds (1) only one muscle is transplanted so that power and function do not compare with those obtained by the transplantation of two or three muscles (2) a good functional result depends upon restoration of thumb function which is not obtained by this method (3) suture of the proximal ends of the divided extensor tendons to the dorsal carpal ligament in order to provide braking action is an inadequate tenodesis because the ligament is already overstretched in most cases of wrist drop because the ligament does not provide a fixed point for tenodesis, and also because the tenodesis becomes overstretched with active hand flexion. The transplanted flexor carpi ulnaris must therefore maintain both hand position and finger function.

JOHN L. LINQUIST M.D.

Observations and Experiences with Tenoplasties for the Improvement of Function in Wrist Drop (Beobachtungen und Erfahrungen bei Sehnenplastiken zur Verbesserung der Funktion der Fallhand)
HERBERT HERBIG *Chirurg* 1938 19 171

Although the results of Bauer's operation for radial paralysis appear to be good and the technique simple the procedure lacks a certain advantage that Sudeck's operation has namely provision for the recovery of radial nerve function and reinnervation of the extensor muscles. Perthes' operation likewise makes no provision for radial nerve regeneration. It is important to carry out early operation in these cases before it can be known whether or not radial nerve regeneration will occur. The author believes that too much value has been placed on rigid tenodesis by Perthes and by other authors in the past and that a more elastic tenodesis as proposed by Bauer is desirable.

The author describes a procedure he used in 4 cases of wrist drop as well as the results obtained in 8 cases treated by Bunnell's method. The author's procedure is recommended especially for cases in which there is a well developed flexor carpi ulnaris muscle. He used a tendon-stripper to isolate the tendons. The flexor carpi ulnaris is isolated and transplanted to the dorsal aspect of the forearm through a channel. Its tendon is then passed through slits made in the tendons of the extensor digiti proprius, the extensor digitorum communis, extensor indicis proprius and extensor pollicis longus and sutured at these slits. The extensor tendons are not cut through. The hand is splinted in dorsiflexion with the fingers in extension for 3 weeks. Because a slight ulnar deviation of the wrist occurred in 2 cases the author added a tendon anastomosis between the flexor carpi radialis and the extensor pollicis brevis and abductor pollicis longus in the fourth case. Ulnar deviation of the wrist did not occur in the last case. The results in 3 cases were satisfactory and in 1 case good. The patients could maintain the hand in balance with extended fingers. There was active dorsiflexion at the wrist of from 20 to 40 degrees and extension of the thumb to 45 degrees. There was powerful closure of the fist with the wrist in dorsiflexion. The period of observation was limited to from 6 to 8 weeks following the operation.

The author reports 6 good results in 8 patients treated by Bunnell's method. In 3 cases abduction of the thumb was unsatisfactory but otherwise the results were good.

In the treatment of wrist drop due to radial paralysis several operative procedures are available ranging from the pure tenoplasty of Bunnell and others to the elastic tenodesis of Bauer and of Sudeck, to the rigid tenodesis of Perthes or to a combination of arthrodesis and tenoplasty. For long-standing cases of paralysis with frank muscular atrophy Perthes' procedure is the only one of value. In cases of recent paralysis with well developed muscles of the arm other procedures should be given more consideration.

JOHN L. LINQUIST M.D.

Experimental Intervertebral Disc Lesions. J ALBERT KEY and LEE T FORD *J Bone Surg* 948 30-A 67

Fourteen dogs were anesthetized and, in each, 4 adjacent discs were exposed. The most caudal disc, usually the seventh lumbar, was designated as Disc 1 and those above it were designated as Discs 2, 3 and 4, respectively.

In Disc 1, by the use of a small tenotomy knife, a square window including the posterior longitudinal ligament and the annulus fibrosus, was removed from the left side of the posterior aspect of the disc. With a small curette, the interspace on the left was vigorously curetted until it bled. The nuclear material and cartilage thus loosened were removed with the curette and with suction. In Disc 2 the same procedure as in Disc 1 was used except that the space was curetted gently and no attempt was made to break through the cartilage plates of the vertebrae. In Disc 3 with the tenotomy knife, an incision was made transversely in the posterior longitudinal ligament and annulus fibrosus on the left side. Some nucleus pulposus material extruded but the disc was not curetted. In Disc 4 a 20-gauge needle was pushed through the annulus fibrosus into the interior of the disc. Spines were obtained from the dogs at intervals varying from 2 days to 28 weeks after operation.

In each Disc 1 (except one) and in each Disc 2 collapse of the disc and narrowing of the disc space were visible in the roentgenograms and in the sagittal sections of the gross specimen. In the latter the soft bulging nucleus was not present. In the older experiments the nucleus was replaced by fibrous tissue. The adjacent nerve roots were adherent to the discs operated upon in every instance and these adhesions were more dense in the experiments of longer duration. In 6 of these roentgenograms, damage to the bone by the curette was visible at Disc 1. Moderate or slight protrusion of the disc

substance at the site of the operative defect was present in 7 of the first discs and 8 of the second discs. In the remaining 13 first and second discs of this group the defect in the annulus was obliterated by fibrin or fibrous tissue and the site of the operative defect was level with or depressed into the disc space.

In the third discs, the incision was found to be closed by fibrin in the dogs sacrificed early and by fibrous tissue in those which had lived long enough for this tissue to form but in the dogs which lived 20, 21, 22 and 23 weeks, a well developed rupture and a protrusion of the nucleus pulposus were found.

In Disc 4 in one instance, a small but definite and characteristic posterior herniation and protrusion of the nucleus pulposus was found at the site of the needle puncture. The adjacent nerve root was slightly adherent to this disc protrusion, and there was slight collapse of this disc with narrowing of the intervertebral space. In the other 13 specimens, there was no definite collapse or narrowing at Disc 4.

Microscopically it was noted that the annulus fibrosus had a very poor blood supply, and that the defects in it tended to heal at the surface while the operative defect in the deeper layers tended to remain open for a long time.

The production of posterior protrusions of the nucleus pulposus appeared to be a slowly progressive phenomenon. The earliest well developed protrusion was noted in a specimen removed 20 weeks after operation.

In none of the experiments was bony ankylosis produced between the bodies of the vertebrae.

The experiments suggest that the primary lesion which leads to a protrusion of an intervertebral disc is a weakening of the posterior portion of the annulus fibrosus. This may be due to degenerative changes or to injury. The degenerative changes in the nucleus pulposus appear to be secondary.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

The Treatment of Spontaneous Prescalenic Aneurysm of the Subclavian Artery (A propos du traitement de l'anéurysme présclénique spontané de la sous-clavière) RENE LERICHE, *J. chir. Par.*, 1948, 64, 81

The author describes in detail an interesting case of aneurysm of the right subclavian artery in a patient suffering from recurring rheumatic fever. The aneurysm was felt as a pulsating mass of hen's egg size. As it involved practically the whole length of the first portion of the artery aneurysmorrhaphy was not practicable and the surgeon decided to ligate the subclavian artery.

An incision was made between the two heads of the sternomastoid muscle and the entire median portion of the scalenus muscle was severed. However the artery coursed so far backward that it could not be visualized, and it was necessary to resect the medial end of the clavicle and to luxate the clavicle downward. The subclavian muscle was cut. Now the vertebral artery was visualized which proved to be greatly enlarged and larger than the subclavian. Ligation of the subclavian artery was done at the origin of the vertebral artery. Uneventful recovery followed.

The patient was seen again 13 months later. The aneurysm had grown slightly and was filled against

Fig. 1. Aneurysm before ligation. An internal mammary artery is seen originating from the sac inferiorly. A bifurcated vessel is superimposed on the sac, evidently the axis thyrocervicocapularis. The other arteries are not visible. Note the lateral diverticulum below the clavicle.

Fig. 2. The sac 16 months after ligation of the subclavian artery. The bilobate appearance is due to the presence of a voluminous mass of fibrin in its middle. The proximal end of the sac is well filled. The first portion of the subclavian artery having been ligated, the filling occurs against the current in a free canal between the clots and the wall of the sac where, normally, blood should pass. The internal mammary artery and a double cervical axis are well visualized.

the current from the axillary artery (Fig. 2). The collateral circulation and the function of the arm were perfect although no radial pulse was palpable.

Three months later that is, 16 months after the ligation the aneurysm was extirpated. A large trunk of the brachial plexus and the phrenic nerve were fused into the wall of the sac and had to be dissected carefully.

In discussing the case, the author believes that it would have been preferable to approach the subclavian artery by the transpleural route and to isolate it close to its origin.

WERNER M. SOLMITZ, M. D.

Progress in Vascular Surgery (Progrès dans la chirurgie vasculaire) R. LERICHE, *Lyon chir.*, 1948, 43, 134.

The author reviews the progress in the various fields of vascular surgery except that of cardio-vascular malformations in which he has had no experience. It is here that the operations of Gross, Alexander Crafoord and Blalock as well as those of Potts

Smith and Gibson have opened a new chapter on catheterisation of the heart.

In cases of acute contusion with peripheral ischemia and absence of pulse arterial puncture is made to insure permeability and novocain is injected into the artery beneath the adventitia to produce a block of the sympathetic ganglion. This block is repeated every 6 hours until the symptoms subside. If however the artery is dilated and contains coagulations immediate arteriotomy is indicated and this is to be followed by repeated sympathetic block. In chronic contusion thrombectomy rather than arteriotomy is recommended.

Wounds from cutting instruments should be sutured, *ven if the circular suture is necessary* and should likewise always be followed by sympathetic infiltration or ganglionectomy. In war wounds of the arteries the arterial wound must be treated *per se*, and without consideration for satellite muscular bone or articular injuries. Arterial continuity must be restored whether by lateral or circular suture or ven by venous grafting. A more frequent use of utures is desirable especially in cases in which ligature is dangerous such as in the primary carotid or common femoral artery but each case has its special indications. However ligature is still done in the majority of cases. Tuffier's intubation with the aid of heparin may be useful in some instances. The reason for the frequent failures of ligature is discussed. Sympathectomy may prevent fatal ischemia with subsequent gangrene. In some cases ganglionectomy is indicated, but the latter must be done promptly before ischemic symptoms develop. Following ligatures which render restoration of the circulation impossible as in the vicinity of a bifurcation, intubation may prove of value. Arteriotomy is therefore usually preferable to ligature. The lower lumen must be examined and if obstructed thrombectomy is indicated.

Aneurysms must be exactly located by arteriography before operation, and although conservative methods may suffice, it is best to prepare the collateral circulation by repeated sympathetic block, or in the larger arteries by ganglionectomy. Preliminary hemostasis is imperative. Digital compression of the governing artery can be definitely useful. In traumatic aneurysms with only one orifice the lateral transarterial angiorrhaphy of Matas is recommended. But, of course, all traumatic aneurysms do not have a single orifice and a lateral sac Endoaneurysmorrhaphy is preferable to excision. It is suggested that the ideal method might be an end-to-end suture following excision or graft. In spontaneous aneurysms with two orifices, the Matas transarterial obliterating angiorrhaphy is preferable to excision. If the aneurysm is at a bifurcation of the vessel it may be best to operate in two stages.

The recent operations of Alexander and Crawford have solved the problem of aortic aneurysm in cases with dilatation subjacent to an isthmus stenosis. In aneurysms above this point preparations for the establishment of a collateral circulation should be

made by a high lumbar or thoracic ganglionectomy. It might be best to make incomplete ligatures at first, to be completed after the collateral circulation has been established but this has been accomplished only experimentally and not in man. For aneurysms below the inferior mesenteric artery at the bifurcation one might completely ligate or divide the aorta without danger following lumbar sympathectomy removing the aneurysm in a second stage. Also derivation by intubation as suggested by Carrell might be tried.

Arteriovenous fistulas must be treated by correction of the short circuit by removal of the fistula. Excision between four ligatures is very well tolerated and may be supplemented by preliminary or subsequent ganglionectomy but this is necessary only in exceptional cases. The ideal method of treatment is by occlusive suture of the fistula after preliminary hemostasis according to Matas and Bickham. Carotid jugular fistulas are too high for suture and will require excision. The procedure is also indicated when there is a sac between the two vessels or as arterial dilatation on the side opposite to the fistula. In some cases the author has been able to resect the sac, placing an almost circular suture in the artery at the level of the tibio-peroneal trunk.

For arterial embolism embolectomy is the procedure of choice but suture of the arterial wound must not be done unless the endothelium is normal. If not, arteriotomy is indicated. Since the advent of heparin embolectomy may be further delayed, and with the use of the Dos Santos deobstruction operation still further delay is possible, so that arteriotomy may soon be indicated only in exceptional cases. If symptoms are due to a small embolus they will subside following bilateral infiltration of the stellate ganglion and the intravenous injection of novocain. Should the symptoms persist a Trendelenburg operation should be performed promptly under local anesthesia.

For thromboarteritis obliterans the first intervention consists of high ganglionectomy and adrenal ectomy followed by ganglionectomy on the opposite side and arteriotomy. For arterial obliteration of the thigh arteriotomy of the iliac artery and the end of the aorta may be followed by ganglionectomy. In cases in which the leg is involved a low ganglionectomy is indicated. In recent obliterations, the author has had very successful results in 5 cases with the Dos Santos deobstruction operation. Nothing new has been added to the treatment of angioma or disoid aneurysm.

On the basis of the excessive growth of limb observed as a result of arteriovenous fistula in infancy the author is experimenting with the creation of a fistula between the superior femoral vessels to correct inequality in the length of the limbs in infants. He also suggests that the creation of an artificial fistula might relieve some cases of persistent hypertension, and that arteriovenous anastomoses might be used to revitalize certain tissues such as the glands of internal secretion. EDITH SCHWARTZ MOORE.

BLOOD TRANSFUSION

Various Articles Concerning Blood Transfusion and Cardiovascular Disturbances in Surgery (Travaux divers sur la transfusion sanguine et les troubles cardio-vasculaires en chirurgie) A HUSTIN *J internat chir., Brux., 1947 1948, 7 & Supp*

The author, director of the surgical department of the municipal hospitals in Brussels, Belgium presents a review of the important work done by himself and his collaborators during the last 30 odd years. About 50 articles on diverse surgical and physiological subjects represent his lifework. In addition to a number of publications on various surgical questions his main interests and the researches of his service were concentrated on two subjects: blood transfusion and cardiovascular disturbances in operations and surgical affections.

He claims to be the first to have performed a blood transfusion with citrated blood (on March 27 1914) several months before this method was published by Lewisohn and Weill in this country. The international discussion concerning the priority of the new method is reported in detail.

In 1937 the author described an apparatus devised to prevent clotting of the blood in the needle and rubber tube, and in 1938 a pump to be used in blood transfusions.

Several articles deal with the questions of transfusion reactions and the influence of the sexes of the donor and recipient on the frequency of their occurrence. In a series of 864 transfusions it was found that the incidence was lowest when both donor and recipient were males (5.3%) and highest when both were female (17.3%). In practice, therefore, it seems advisable to 'cross' sexes in order to reduce the cases of untoward reactions. Another set of statistics covering 3 881 transfusions proved that reactions of all kinds are not more frequent after the second and third transfusions than after the first one. The author concludes that, except for special indications, the determination of the Rh factor is not necessary before transfusion.

Another large group of researches was devoted to cardiovascular problems. Changes of heart frequency during anaesthesia and during surgical operations were studied by means of a cardi tachy meter. This instrument invented by the author registers automatically the R waves of the electrocardiogram and permits study of the changes of heart frequency during inhalation as well as during spinal and local anaesthesia. Furthermore the influence of various surgical operations and nonsurgical factors (emotions, cough, change of position) on the heart frequency were studied with the aid of this instrument.

In order to study the reactions of the vasomotor system under various conditions the author devised an apparatus which makes it possible to register

automatically and simultaneously the temperature of different parts of the body e.g. rectum, hand and foot. Experiments on normal persons who were kept in bed revealed that the skin temperature of the extremities undergoes characteristic rhythmical changes during the daily cycle. During the night the temperature of the uncovered foot follows the rectal temperature closely. Around 5.30 a.m. the curve goes down brusquely by about 5 degrees centigrade and continues on this low level through the day only to rise again around 8 p.m. This typical curve is observed consistently whether the individual is awake or asleep.

Other studies deal with the effect of cooling of one member on the vasomotors of the contralateral limb, the influence of tourniquet, of emotional stimuli of arterial embolism and other pathological factors on the skin temperature of the affected parts. Furthermore changes of skin temperature after sympathectomy and other neurosurgical interventions in chronic obliterating arteritis and intermittent claudication, in phlegmasia alba dolens during different types of anaesthesia and operations were studied.

This short review gives only an incomplete picture of the many-sided work of Hustin. His publications include a wide range of other subjects in surgery and anaesthesiology. WERNER M. SOLOMITZ, M.D.

A Study in Intravascular Thrombosis with Some New Conceptions of the Mechanism of Coagulation. HAROLD CUMMINS and RAYMOND N. LYONS. *Brit J Surg.* 1948 35 337

Postoperative thrombosis may be divided into three classes:

1. Immediate postoperative thrombosis (i.e. within 24 hours) presumably due to the formation of a considerable amount of intravenous thrombin during an extremely long operation by excessive tissue trauma.

2. Delayed postoperative thrombosis indirectly caused by the presence of fibrinogen B associated with venous stasis. These factors cause platelet disintegration and intravenous thrombin is formed. Stasis again plays a part in preventing the normal metabolism of the fibrin which is formed.

3. The mechanical detachment of embolic fragments.

Contributing factors in the second type appear to be pyogenic infection and/or tissue necrosis \rightarrow fibrinogen B in circulating blood + platelets \rightarrow increased platelet fragility + venous stasis \rightarrow intra-venous thromboplastin \rightarrow intravenous thrombin (low coagulation time) \rightarrow fibrin + stasis \rightarrow thrombosis.

Both fibrinogen B and profibrin are factors which increase the blood sedimentation rate. And tests of their clinical determination are described.

JOHN J. MAULSRY, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Movement of the Diaphragm after Operation JONES
HOWARD. *Lancet* Lond., 948, 85.

The author investigated the high incidence of chest complications after operations for hernia in a group of 135 young army personnel. Preoperative and postoperative medication was standardized. One day prior to operation the vital capacity, the chest expansion and the diaphragmatic excursions were measured. These data were also obtained in the postoperative phase of each case. In this series spinal anesthesia was used in more than half of the patients. Nevertheless postoperative chest complications were as high as with any type of inhalation anesthetic.

The lower limit of diaphragmatic excursion was 1.5 cm. and the average 5 cm. The incidence of chest complications in association with a 3 cm. diminution of diaphragmatic excursion was 44 per cent, with a 2 cm. diminution 50 per cent, and with a 1 centimeter diminution 20 per cent. It was concluded, therefore, that the incidence of chest complications was associated with the postoperative reduction in diaphragmatic movement. It was not possible to determine whether restriction in diaphragmatic excursion caused atelectasis or whether the atelectasis preceded the inhibition in diaphragm movement. However radiologic evidence of diaphragm pathology was demonstrable before any clinical evidence of lung pathology. There was no specific relationship between the site of operation and the side of diaphragm involvement. In the majority of cases in this series the diaphragm was affected on both sides. Vital capacity was reduced postoperatively from 5 to 50 per cent. Not all cases with diminished vital capacity showed alterations in diaphragm excursion. The latter can be accounted for on the basis of compensatory activity by other respiratory muscles. Postoperative serial roentgenograms of the chest revealed that partial or complete atelectasis was confined to the lower regions of the lung. Apical lung changes were never observed.

The diaphragm is intimately co-ordinated with the intercostal muscles and the muscles of the abdominal wall all of which are innervated by the respiratory center, the fibers of the spinal cord, the thoracic nerves, and the phrenic nerve. In the erect position the abdominal viscera exert a negative pressure on the under surface of the diaphragm. In the supine position negative pressure is released and the diaphragm rises. The right hemidiaphragm averages 1.25 cm. higher than the left. The total excursion of both hemidiaphragms is approximately the same. The total excursion averages 1.25 cm. more in the supine and prone positions as compared with the erect, and averages 3 cm. less in the sitting position

as compared with the supine. With the patient on his side the diaphragm pivots about the spine, the upper hemidiaphragm moving slightly the lower moving markedly.

A knowledge of the physiology of the diaphragm is of clinical value in postoperative care so as to increase diaphragmatic excursions and influence expansion of various parts of the lung. The sitting position or Fowler's position is considered detrimental for the postoperative case because of its effect on the diaphragm and lung. The abdominal wall should be permitted maximal freedom of action unhampered by tight dressings or abdominal binders. Full and free pulmonary ventilation can be obtained by encouraging active movement of the patient in bed and/or early ambulation. Attention to postural drainage should be directed toward the lung bases by elevation of the foot of the bed or by keeping the patient flat and getting him to turn from side to side. Patients should be taught to breathe correctly and preoperative and postoperative breathing exercises routinely enforced in the wards. All respiratory depressant drugs should be discontinued postoperatively and aspirin and bromides substituted as analgesics. Smokers should abstain from smoking for a few days preoperatively because of their predisposition to chest complications. In elective surgery the infective element can be reduced by delaying operation in patients with upper respiratory colds and the proper isolation of patients in surgical wards. In inhalation anesthesia, sterilization of the breathing apparatus is an important safety factor.

BENJAMIN G. P. SKATEOFF, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Comparison of Crash Injuries in Man and in Laboratory Animals. ROBERT F. ROSENBERG and
GEORGE M. HARR. *Am J Surg* 943, 76-84.

The authors compare observations made on humans beings coming to autopsy following aircraft accidents with the observations of lesions produced experimentally on cats, rabbits and mice. They selected 21 victims who had apparently been seated facing forward at the moment of impact of the aircraft in the ground. All of the victims of these crashes had been killed instantly with the exception of 6 involved in crash landings which occurred when the plane was moving between 50 and 90 miles per hour. A group of 9 victims were known to have survived long enough to reach a hospital. The duration of survival ranged from 15 to 80 hours.

Comparative experiments were done on anesthetized cats, rabbits, and mice by abrupt deceleration of the animals. In spite of many differences in the conditions obtained during the deceleration, the lungs revealed gross pathologic changes in more than

75 per cent of both the human beings and the experimental animals

In general, the types of lesions in the lungs, liver, spleen, diaphragm, kidneys, gastrointestinal tract, and pancreas were similar in man and the laboratory animal. The incidence and severity of the lesions were considerably greater in human victims who died instantly. Extensive trauma to the brain, heart, and great vessels was not observed in the experimental animals.

These findings indicate that direct experimentation on laboratory animals can be a valuable adjunct in the study of the mechanisms of production of internal injuries and possibly also in designing methods of protection against great decelerative forces.

LEROY J. KLEINBAUER, M.D.

The Management of Whole Thickness Burns with Involvement of the Bones and Tendons. HARVEY S. ALLEN, *Q. Bull. Northwest Univ. M. School* 1948, 22: 115

Whole thickness burns are often complicated by the involvement of bone or tendon within the depths of the wound. The neglect of closure of these open wounds has meant increased loss of protein and superimposed infection and frequently the patient is in danger of loss of limb or even life. Constantly added infection will mean an increase in destruction of the soft parts and also of the bone or tendon. The patient's condition will rapidly deteriorate in the presence of this infection. Weight loss, cachexia, extreme secondary anemia and hypoproteinemia rapidly develop. The patient's condition can be improved by the usual methods of proper diet, liberal use of transfusions of whole blood and by combating the infection with scrupulous aseptic care of the open wound. To restore these patients to a satisfactory status which allows closure by skin graft to the wound is a very real undertaking. When a planned attack in the care of these deep burns is utilized it is often possible to obtain early closure in from 10 to 14 days after the injury. However there must be a minimum of delay between the time of removal of the burn slough and the application of the skin graft. If at the time of skin grafting the tendon still retains its sheath or its normal color a split graft applied over it will heal satisfactorily. It will at least seal the wound from subsequent infection. This is also done when exposed bone has retained intact periosteum. If the tendon is necrotic or has changed color to yellow or black excision of the necrotic portion is essential before a graft will survive over it. When it is obvious that the exposed bone has lost its periosteum or if it has become infected then a skin graft will not heal over it. Also it is inadvisable to attempt to remove dead and infected bone down to healthy tissue. Sufficient time must be allowed to elapse for the infected bone to sequestrate. The adjacent soft tissue wound should not be ignored or neglected while the demarcation of bone or tendon is taking place. The soft tissue wound itself should be closed by skin grafting up to the site of necrotic bone or tendon. After se-

questration of these structures has occurred the remaining small wound may be grafted and closed.

FRANK F. KANTHAKE, M.D.

Reconstruction of the Burned Hand. RADFORD C. TANZER, *England J. M.*, 1948, 233: 687

Reconstruction of the burned hand starts at the time of the initial dressing. The immediate local treatment of a burned hand includes a minimal debridement confined at most to the removal of blisters and the application of a firm even pressure dressing. The fingers are dressed individually and the hand is held in the position of function.

The method of immediate or early excision of severely burned areas and replacement with free skin grafts rarely applies to the burned hand because of the anatomical features of the hand with its dearth of subcutaneous tissues. Such a dissection would leave important structures such as the tendons and aponeuroses of the fingers for the bed of the graft. Pyruvic acid paste or moist dressings may be used to prepare the wound for grafting.

Any granulating area should be resurfaced as soon as the nutrition of the wound permits. Early mobilization as early as possible, to minimize edema and maintain joint action should be started even before the grafts are stabilized. This is the best time to correct incipient contractures by proper positioning of the digits on a splint with gentle elastic traction at strategic points to maintain the functional position. Once the skin is stabilized one can start occupational therapy and await softening of the scar before considering a more permanent replacement. Often no further replacement will be necessary.

In the later reconstruction one should be sure the process has become stationary. One type seen is the spotty depigmentation of the dorsum which may offer sufficient reason for replacement. Hypertrophic keloid is a common late complication.

The principal indication for resurfacing is the presence of a constricting or an unstable scar. A most satisfactory type of graft is of nearly full thickness which is dissected from the abdominal wall; however it is time-consuming and requires an extensive procedure so for expediency the dermatome or free hand split thickness graft is usually employed. The method employed in resurfacing the dorsum of the hand is described.

Direct pedicled flaps are advisable when tendons or joint capsules are involved and may require further reconstructive work. Burns to the volar surface of the hands if deep present baffling problems in restoration. Occasionally free grafts will suffice if the tendon sheaths are preserved but otherwise the pedicled grafts will be required.

Residual joint contractures may be produced by either the lack of splinting or improper splinting either of which may result in complex contractures of the digits. These deformities may be corrected by elastic splinting or if this fails by capsulotomy.

Flattening of the thumb with adduction contracture may be minimized by early and effective splint

ing, provided the muscles have not become shortened or fibrotic. If the contracture is of long standing the condition can be improved by detaching the adductors from their insertion distally and reattaching them proximally on the metacarpal to deepen the web and permit the thumb to fall into a more abducted position.

HARVEY S. ALLEN, M.D.

Postoperative Illness (La malaltia postoperatoria)
FRANCO B. ARCEL. *Arch. Ital. Med. pp. digest.* 1948, 4: 77

Any surgical intervention however minimal produces in the organism a series of local and general alterations which constitute postoperative illness, *malaltia postoperatoria*, a term introduced by Leriche in 1934 to indicate this syndrome. The symptoms may be mild or grave. In the mild form one sees general malaise, dryness of the mouth, thirst, vomiting, anorexia, paralysis and distention of the intestines, mild hypotension, oliguria, insomnia, psychic agitation and genital disturbances. In the more severe grade there are two forms: a precocious form (shock) and a late form (toxic) with correspondingly more severe symptoms.

Review of the literature reveals at least eight theories on this postoperative illness, to which the author adds a ninth based on the anatomy. This theory of Antonucci *et al.* contends that the anatomical lesions, however small, in the various organs, especially in the liver and kidney, may be the basis for the postoperative neurohumoral syndrome. Antonucci observed that when aspiration was done following gastric resection there were no toxic manifestations or elevation of the blood nitrogen. Research by his students consisting of injecting rabbits with fluid withdrawn from the stomach 24 hours after resection showed marked toxicity in these animals. Histology showed marked congestion, hemorrhage, anemic and hemorrhagic infarcts, and necrosis in the internal organs, especially in the liver. The work of Roger and Garnier on normal gastrointestinal liquid is mentioned. These authors concluded that normal gastric juice was mildly toxic while the fluid from the intestine was much more toxic, that from the small bowel being more toxic than that from the colon.

The authors performed experiments by injecting fluid aspirated from patients who had had a Reichel Polya gastric resection from 20 to 24 hours before. This fluid was collected with aseptic precautions, passed through Chamberland and Berkefeld filters, and then injected into the marginal vein of the ear of rabbits in varying doses. Five different groups were used. It was concluded that gastric retention following gastric resection is very toxic and that systematic aspirations one or more times a day should be made in the period immediately following operation. The fluid aspirated after the first 24 hours is less toxic. If the aspirated fluid is kept at ambient or atmospheric temperature the toxicity also diminishes. It was also found that gastric juice from normal patients or those with peptic ulcer was

not toxic or only mildly so even after the injection of 1 mgm. of histamine.

The toxicity is believed to be due for the most part to histamine and also to other substances such as polypeptides and peptones.

The anatomicohistological lesions are caused by alterations in the circulation and blood and consist essentially of thrombosis and cloudy degeneration most marked in the liver and kidneys.

LUIGI J. FROVOTTI, M.D.

ANESTHESIA

Trends in Regional Anesthesia. CARL S. HELLMAN and RALPH M. TOVELL. *A.esthesiology* 1948, 9: 400

Regional anesthesia has been profoundly affected by the introduction of new agents and improved methods of administration of standard drugs. The methods most frequently in the public and professional eye are discussed.

The introduction of balanced anesthesia contributed to a renewal of interest in spinal anesthesia. The development of continuous spinal techniques has made possible a revolution in thinking in regard to agents and methods for this type of anesthesia. Recently the greatest amount of time and thought given to any one technique has been devoted to the valuation of continuous caudal analgesia. Many of the over-all complications originally reported are now avoided by the judicious selection of patients. It is likely that the more frequent use of balanced anesthesia may contribute an increased measure of safety and efficiency to the procedure.

Procaine is still the agent of choice. Repeated comparative studies have demonstrated the relative safety of this drug. As a vasoconstrictor capable of producing a local reaction without untoward systemic effects, cocaine has proved its value. The concentration of procaine in solution is varied according to the type of block employed. The maximal safe dose is considered to be 1.0 gm. of the drug.

It is evident that regional methods still have an important place in the practice of anesthesiology. Frequently they are combined with other methods to meet the needs of patient, surgeon and anesthetist.

MARY FRANCES POSE, M.D.

Psyche-Sparing Anesthesia (Psychoschoonende Anesthe) H. SCHLOERMOGEN. *Chirurg* 1948, 9: 43

The author stresses the importance of planning an anesthetic sequence which will not only spare the patient pain during the operation, but also the psychic trauma attending any operative procedure. He first suggests discussion of the anesthetic freely with the patient. If the patient has had an uncomfortable experience with a previous anesthetic, it is wise to change the medium, or at least to reassure him that the discomforts will be avoided this time. The ideal anesthesia would be one which would start as soon as the patient is prepared for the operation, and continue until all of the postoperative dis-

truss has been passed. This is, of course, impossible but it is an ideal status which should be desired in the future.

The most perfect anesthetic from the standpoint of the patient's psychic state, in the author's opinion, is rectal avertin. Unfortunately the use of this medium is attended by too high a mortality and morbidity to make it generally practicable. In the author's series of 10,000 cases there were 4 fatalities which might be attributed to the drug. Therefore at the present time the intravenous use of barbiturates with constant administration through tubing appears to be the best procedure.

WILLIAM C. BECK, M.D.

Trichlorethylene (Trilene) as an Anesthetic in Neurosurgery G. J. C. BRITAIN *Current Res. Anesth.*, 1948, 27, 145

During the past 3 years trichlorethylene (trilene) has been used in the E. M. S. Neurosurgical Unit for more than 250 major operations embracing a wide range of cases. The anesthesia technique is described. A minimum of apparatus is used. The trichlorethylene is given as an adjuvant to nitrous oxide and oxygen.

The advantages of the method include the complete absence of toxic effects on the cardiovascular system, liver or kidney; the lack of anoxemia; less capillary bleeding than when nitrous oxide, oxygen or cyclopropane is used alone; and complete elimination of the explosion hazard. There is no struggling, straining or coughing during induction.

The technique involves the spraying of the nose, pharynx, and vocal cords with a 1 per cent nupercaine followed by an induction with sodium pentothal and direct vision endotracheal intubation. Anesthesia then is maintained with nitrous oxide and oxygen, with a minimum of trichlorethylene. The method

has been used in poor risk cases and in children. Eight illustrative cases are briefly described.

MARY KARP, M.D.

Oxygen Therapy in Surgery WENDELL H. KLEWER. *Am. J. Surg.* 1948, 76, 76

This article presents a discussion of the therapeutic value of oxygen in surgery. A brief review of the physiology of respiration is given including the effects of carbon dioxide excess and oxygen lack. The types of anoxia are enumerated and there is presented a brief historical review of the use of oxygen in therapeutics. In any consideration of oxygen therapy in surgery it is well to keep in mind the fact that the drugs most widely used in surgery—morphine, scopolamine and the barbiturates—exert a depressing effect on the respiratory center. Those surgical conditions are considered for which oxygen therapy is especially beneficial. They are head injuries, shock, postoperative ileus, postoperative pulmonary complications, thoracic wounds, pulmonary burns, thyrotoxicosis and anesthesia.

Seven per cent carbon dioxide and 93 per cent oxygen is of greater value than pure oxygen alone because from 5 to 7 per cent carbon dioxide with oxygen increases the cerebral blood flow up to an average of 75 per cent and it also increases pulmonary ventilation.

Adequate blood replacement during surgery and the use of oxygen, especially if an inhalation anesthetic is used, should be resorted to both in the operating room and postoperatively. It must be remembered that cyanosis and dyspnea are not present in the early stage in the development of anoxia. The use of 7 per cent carbon dioxide and 93 per cent oxygen mixture as a preventive and therapeutic aid for anoxia is not as widespread in surgery as it should be.

ROENTGENOLOGY

Certain Images of Striae in Pulmonary Fields (Sopra alcune immagini strie nei campi polmonari)
M. UGO PIEMONTE. *Red. di med. Milano*, 1943 34-193

Among the various striae visible in roentgenograms of pulmonary fields, three are of clinical importance:

1. Fleischner's striae or basal striae of lamellary atelectasis. These have a horizontal direction and are usually from 15 to 16 cm. long and approximately 3 mm. wide. They are usually located in the lower third of the pulmonary field, in proximity to the diaphragmatic vault and less frequently in the middle third. They may be unilateral or bilateral, and are more frequently found on the right side than on the left. As to their pathogenesis, they are caused by a so-called directional collapse which in turn is due to several factors such as retraction of the lungs and resistance of the lungs, pleura and the thoracic wall.

The differential diagnosis must consider two conditions: horizontal striae of pleural origin and parenchymal fibrosis. A rapid disappearance of the striae and their location in the lower portion of the lungs support the diagnosis of Fleischner's striae.

2. Reichmann's striae or "rainy streaks." A coalescence of nodules produced by silicosis may produce shrinkage which leads to the formation of indentations and folds in the lungs. In roentgenograms such formations produce striae extending from areas of shadows to the diaphragm and resembling streaks of rain. Angular elevation of the diaphragm may result. Autopsies in such cases fail to demonstrate pathologic bands and adhesions between the lungs and the diaphragm.

Unlike striae caused by other pulmonary processes, Reichmann's striae do not originate in the hilus but are directed from extensive areas of increased density straight downward.

3. Striae according to the author's studies on cadavers may be of interlober pleural origin. Such striae have been observed by the author in 50 per cent of infantile lungs. Such striae may be caused by an accessory posterior lobe or by a minute hyperplasia of the epithelial layer accompanying congestion and slight exudative processes. Partial synchysis, partial pneumothorax, slight accumulations of fluid between the lobes, or circumscribed pleurisy may also produce striated images.

ARISTO F. CINOLLA, M.D.

J. Jejuno-gastric Intussusception. A Rare Complication of the Operative Stomach. STEN ALMGREN. *Acta med. Stockh.*, 1943, 29 353.

Jejuno-gastric intussusception is apparently a rare complication after stomach operations for on review of the literature the author found only about 70 re-

corded cases since Bozal first described the condition in 1914, and in only 3 of these was partial gastrectomy done, the other cases having occurred after simple anterior or posterior gastroenterostomy with or without enteroenterostomy. Only 12 of the 70 odd cases were diagnosed first roentgenologically apparently because few of the patients were subjected to examination with radiopaque media. The author presents the thirteenth case so diagnosed.

The patient had a partial gastric resection by the Billroth II Polya technique with posterior gastroenterostomy at Sabbatsberg Hospital, Stockholm, in 1937 because of a recurrent duodenal ulcer. He was then symptom-free until 1940 when he became acutely ill several hours after a crayfish dinner during which he took several strong drinks. The attack began with nausea and vomiting; a little later cramping epigastric pain developed at intervals of 5 to 10 minutes relieved by vomiting of food at first, then bile then blood. There was no bowel movement but gas was passed. An abdominal roentgenogram taken on the day of entry showed nothing of note and several days later the cholecystogram was normal. The urine showed an increased diastase content, and this prompted a diagnosis of acute gastroenteritis and pancreatitis. The attack subsided in 3 days.

The patient was then well until June of 1946 when he was readmitted with a precisely similar attack except that it was not preceded by dietary excess nor accompanied by increased urinary diastase. The abdomen was soft, but in the left epigastrium there was active muscular contraction and marked tenderness. An abdominal film again showed no definite pathology, but when barium was given orally a large intragastric filling defect was seen protruding into the stomach from the stomal site and presenting the typical pattern of the folds of Kerkrag outlined by barium. Jejuno-gastric intussusception was diagnosed and confirmed at operation an hour later when approximately 50 cm. of the efferent loop of the jejunum was found to be invaginated into the stomach and easily reduced. The gastric stump and the afferent loop were widened, but nothing else unusual was noted; the stoma was the width of about 2 fingers. Except for a minor attack of pain in October 1946 the patient was free of distress during the subsequent year.

Since the 1940 attack was practically identical with that in 1946, it is now assumed that the former episode also was due to gastrojejunal intussusception which eventually underwent spontaneous reduction. Prolonged blockage of the duodenal loop during the first attack is thought to have been responsible for the increased urinary diastase level at that time.

In addition to the acute cases such as described, which carry a grave prognosis necessitating prompt operation, the literature records chronic cases characterized by a feeling of fullness in the epigastrium

shortly after meals and frequently associated with mild vomiting and sometimes with cramping epigastric distress. Recovery usually occurs within an hour or two. Such cases may be examined roentgenologically on repeated occasions without the discovery of an abnormality and then more or less by chance a subsequent roentgenogram may reveal an intussusception. Reduction was watched fluoroscopically in one chronic case. At operation the roentgen-demonstrated intussusception may or may not still be present in some cases the phenomenon has been induced during operation.

The intussusception may involve the afferent limb of the anastomotic jejunal loop only the efferent limb only or both (combined type). The size of the stoma has varied widely. Neither at the exploratory laparotomy nor at autopsy has an anatomicopathological lesion been found to account for the production of the phenomenon and the cause is therefore assumed to be functional. Involvement of the efferent loop is commonest in the recorded cases and apt to lead to more severe symptoms than afferent involvement. The simple one-limb type is usually of late onset, the average interval after operation being 6 years. The combined type of intussusception which is essentially a prolapse of the jejunum through the gastric stoma is the type usually found as an immediate postoperative complication. The author has seen such a case through the courtesy of E. Perman. The diagnosis was missed originally in 1924 but the old films are now believed to be diagnostic. This discovery increases to 5 the number of cases of gastrojejunal intussusception reported after partial gastrectomy.

Only 18 of the cases in the literature were examined with radiopaque media. The diagnosis was made as a result of the procedure in 12 instances, and a review of the films shows that it could have been made in 3 more cases. Another case showed only failure of gastric emptying. Early diagnosis is vital in patients with acute gastrojejunal intussusception since operative delay beyond 48 hours is said to increase the mortality to 50 per cent. Unless there is a palpable intussusciens however the diagnosis is rarely made clinically. Therefore the author urges that contrast media be employed whenever possible in patients who have developed upper gastrointestinal symptoms following gastric operations.

LILIAN DONALDSON M.D.

The Case for Functional Cholecystography Comparative Studies on the Aqueous Oral and the Bronner Tests, both Administered to the Same Normal Healthy Subject (In merito ad una colistografia funzionale. Ricerche comparative fra la prova idrica orale e la prova di Bronner in medesimi soggetti normali) FRANCO HUNGER. *Radiol. med.*, Milano 1948 34 263.

Nothing a disagreement between Casati (*Radiol. med.* 1946 pp 33 and 448) and P. Buisson (*Radiol. med.* 1946, p. 298) as to the relative merits respectively of the aqueous oral and the Bronner tests as

an adjunct to the usual cholecystographic technique using the ordinary intravenous contrast media the author was able to complete comparative studies on 12 normal individuals. The technique consisted in the administration of a glass of water at ordinary room temperature (aqueous oral test) followed 2 or 3 days later by a repetition of the cholecystography with the administration of crude egg yolk (Bronner test) at the moment of injection of the contrast medium with roentgenograms taken at intervals of 0, 5, 10, 15, 20, 30 and 60 minutes thereafter. The phenomena sought to be compared were the increase under stimulus, in the opacity of the shadow of the gall bladder and in the promptness of onset and extent of the induced motor activity of the organ.

On the whole the evidences of increased contraction of the shadow cast by the contrast media were obtained or were absent indifferently with either the aqueous oral or the Bronner tests. No constant relationship could be observed between the shadow increase and any modification (contraction) of the bladder morphology. With regard to the motor activity induced in the organ under these methods of stimulation a moderate amount of contractile stimulation could be observed rather regularly with the aqueous test however this phenomenon could not be compared in intensity and thoroughness with the complete and progressive emptying of the gall bladder under the stimulus of the egg yolk.

From these results the author concludes that at least from the normal dynamic standpoint the Bronner test is of greater practical value in cholecystography.

JOHN W. BRENNAN M.D.

Roentgenologic Changes in the Urinary Bladder and the Distal Portion of the Ureters in Spermatocystitis. GUNNAR EDSSON. *Acta radiol.*, Stockh., 1948, 29 371.

In a group of urethrocytographic examinations made at the Caroline Hospital in Stockholm on various clinical grounds some of the cystograms showed localized irregular indentations of the mucosal surface of the inferoposterior aspect of the fundus of the urinary bladder. The irregularities were either finely jagged or more coarsely nodular. The appearance suggested an inflammatory process in the region where the seminal vesicles are closely applied to the urinary bladder, and a spermatocystitis was therefore considered the probable explanation. Subsequent investigation including rectal and cystoscopic examinations confirmed this suspicion.

Cystoscopists have called attention to local basal cystitis as a manifestation of infection of the underlying seminal vesicles, but the author in reviewing the literature did not find that this cystographic change was recognized as a diagnostic sign of spermatocystitis or perispermatoctitis. He regards the sign as of some importance because while other associated diseases usually of the prostate or urethra, are often the first to draw attention the spermatocystitis, which may be easily overlooked on clinical grounds, contributes greatly to the patient's distress in many instances.

JOHN W. BRENNAN M.D.

Roentgenologic Changes in the Urinary Bladder and the Distal Portion of the Ureters in Spermatocystitis. GUNNAR EDELMAN. *Acta radiol.*, Stockh. 1948, 29 371

In a group of urethrocytographic examinations made at the Caroline Hospital in Stockholm on various clinical grounds some of the cystograms showed localized irregular indentations of the mucosal surface of the inferoposterior aspect of the fundus of the urinary bladder. The irregularities were either finely jagged or more coarsely nodular. The appearance suggested an inflammatory process in the region where the seminal vesicles are closely applied to the urinary bladder and a spermatocystitis was therefore considered the probable explanation. Subsequent investigation, including rectal and cystoscopic examinations confirmed this suspicion.

Cystoscopists have called attention to local basal cystitis as a manifestation of infection of the underlying seminal vesicles but the author in reviewing the literature did not find that this cystographic change was recognized as a diagnostic sign of spermatocystitis or penspermatocystitis. He regards the sign as of some importance because while other associated diseases, usually of the prostate or urethra are often the first to draw attention the spermatocystitis which may be easily overlooked on clinical grounds, contributes greatly to the patient's distress in many instances.

Six cases are presented, 5 of them in some detail. All the patients were adult, their ages ranging from 26 to 4 years. Five of the patients were admitted with one or more of the following complaints: perineal or low unilateral abdominal pain, acute tenesmus and smarting pain on urination and marked urinary urgency and frequency. In each case the cystographic changes were the same as those described and confirmation was obtained either by rectal palpation and cystoscopic examination or by autopsy of the presence of a diffusely enlarged tender seminal vesicle with edema and hyperemia of the mucosa of the overlying urinary bladder. The prostate in these cases was either normal to palpation, or more often moderately enlarged, firm and well circumscribed. In one case the inflammation extended posteriorly to involve the rectum as demonstrated both radiographically and by direct inspection. Four months later the patient was asymptomatic and both the rectal and cystographic inflammatory signs had disappeared. The sixth case was one of acute urinary retention secondary to urethral strictures resulting from gonococcal infection many years earlier and the urethrocytographic demonstration of local change in the posterior portion of the urinary bladder was regarded as of minor importance.

Spermatocystitis may also cause inflammatory changes in the ureter leading to ureterostenosis particularly in those individuals in whom the most distal portion of the ureter is in intimate contact with the seminal vesicle for a distance of a centimeter or more and in whom the process has become chronic.

The author presents 4 cases, one of them from the group mentioned in which hydroureter and hydronephrosis were found in the absence of evidence of calcified stone and in which roentgenograms demonstrated stricture from 1 to 4 cm. long in the most distal portion of the ureter. Rectal examination revealed diffuse tender enlargement and infiltration at the site of the seminal vesicle on the right and cystoscopy showed unilateral localized trigonal edema and redness of the mucosa of the urinary bladder on that side especially in the region of the ureteral orifice about the internal urethral sphincter. Probing of the ejaculatory duct in one case caused pain to gush forth. The hydronephrosis was so great in another of these cases that nephrectomy was deemed advisable and at operation the roentgen findings were confirmed and evidence of uretinitis at the site of stricture was established. The presenting complaint in these cases was periodic pain and trailing urination in one instance accompanied by chills on urinating. An old history of gonorrhea was obtained from 2 of the patients.

While H. Lat and Merricks, among others, have mentioned the ureterostenosing effect of spermatocystitis little consideration has been given to it in radiological literature. The author suggests that if the possibility of this type of stricture is kept in mind in dealing with cases of unexplained dilatation of the renal pelvis and ureter the condition may be found more frequently. Lutz Do. LEONARD M. D.

Anomalies of the Spine in Anomalies of Viscera and Constitution. JOURNAL TO CHIRURGIA 10. 1918. Stockholm. 045, 20. 3.

Anomalies of the spine are frequently encountered in association with visceral and constitutional anomalies. In amphibia there is a direct relationship between the notochord and the dorsal lip of the blastophore.

Two cases of sirenomorph monsters with a lumbosacral defect, scoliosis of the spine, imperforate anus and malformation of the urinary tract are described. These cases denote a relationship of the primitive streak and the notochord in visceral development. Seven cases of visceral invagination and anomalies of the spine are described. In many of the latter there are signs of hormone imbalance: hirsutism, diabetes, and excess adipose tissue. In such instances the associated anomalies rest between the hypothalamus, thalamus, and anomalies of the spine.

The roentgen findings support the author's contention that in man, as in amphibia, there is a developmental relationship between the notochord and the viscera. MAURICE D. SACHS, M.D.

Roentgendagnostic Points of View of Spinal Tumors in Children. OULU OULU. 10. 1918. Stockholm. 1918, 20. 79.

Spinal tumors in children are infrequent. However the diagnosis of spinal or extradural tumors should be kept in mind in instances of undiagnosed back pain.

Roentgenograms depicting extradural cysts or tumors reveal pedicle erosion, widening of the interpedicular space, rarefaction of the laminae and erosion of the body of the vertebrae. Delay of ossification center closures due to increased intraspinal pressure and kyphoscoliosis in spinal extradural cysts may be present.

Two cases, one of extradural cyst and one of intramedullary osteocytoma, diagnosed by means of roentgenograms plus clinical examinations are reported.

M. URBECK D. SACHS, M.D.

Vacuum Intervertebral Discs. E. H. SAMUEL. Brit J Radiol. 045. 337.

In 3 patients referred for roentgenograms of the lumbosacral spine because of low backache lateral views showed a linear streak of radiolucency in the center of the lumbar disc. This was interpreted as a transitory accumulation of gas derived from the blood stream, which had seeped into the center of the disc to fill the vacuum created when the disc had suffered degeneration and loss of the nucleus pulposus was put under strain. The author accepted the finding of such an accumulation of gas as pathognomonic of disc degeneration but agreed with Magnusson, who first described the phenomenon, that the gas itself does not cause clinical symptoms. Its presence is fleeting for it disappears whenever the strain is taken off the disc by allowing the patient to assume a less lordotic horizontal, or the erect, position.

The 3 cases of vacuum disc presented in this article occurred in 2 men and 1 woman aged respectively 71, 54 and 66 years. In each case there was narrowing of the lumbosacral space and osteophyte formation on the adjoining vertebral bodies which were regarded as associated signs of disc degeneration. The neurological examination was negative.

LILIAN DONALDSON, M.D.

The Roentgen Changes Produced by Diffuse Torulosis in the Newborn. EDWARD B. D. NEUBAUER and ARTHUR TUCKER. *Am. J. Roentg.* 1948 50 203

The authors describe 3 cases of torulosis with roentgenological findings. The condition is a relatively rare subacute or chronic infection caused by the *Torula histolytica* (*Cryptococcus neoformans*), a fungus that is occasionally found on normal skin and in the feces and occasionally appears to inhabit the female genital tract although it has been often thought that these cryptococci were not pathogenic. More than 100 cases of torula meningoencephalitis or diffuse torulosis have been reported but none of the patients have been under the age of 3 years and only 4 have been reported who were under the age of 10 years. Torula may invade the lungs, skin, joints and subcutaneous tissues but most frequently involves the central nervous system. In the 3 patients described the infection probably occurred either during intrauterine life or at the time of delivery. The damage produced by the fungus was severe and was fatal to all 3 infants within a few weeks after birth. Each of the infants showed evidence of mild hydrocephalus and diffuse punctate and confluent calcification of the severely degenerated brain on roentgenographic examination. The calcification resembles that seen in toxoplasmic encephalitis. Enlargement of the liver and spleen was present in each patient. Two patients showed inflammatory and granulomatous lesions in the lungs and 2 showed non-specific submetaphyseal decalcification in the long bones.

FRANK L. HUSKEY, M.D.

Penile Carcinoma. A Review of 43 Cases Treated at Bellevue Hospital During the Past 25 Years. JOSEPH ZAUSSER. *Radiology* 1948 50 746

Although the number of cases of penile carcinoma reviewed is rather small for statistical purposes, some worthwhile conclusions can be drawn on certain phases of this condition.

A study of its incidence shows that circumcision at an early age seems to offer protection against the development of the disease.

The average age at the onset of symptoms was 42 years, the largest number of cases occurring in patients in the sixth decade.

The most important etiologic factors were phimosis or paraphimosis with insuppressed smegma which occurred in 52 per cent of the cases and syphilis, which occurred in 29 per cent. In 12 cases no laboratory tests were made.

The primary lesion was located on the glans in 12 cases, the coronal sulcus in 7 cases, the shaft in 7

cases and the prepuce in 4. It was unrecorded in 4 cases. Nine of the patients had a previous penilectomy.

Metastases to the inguinal nodes were noted in 70 per cent of the cases at the initial examination. In a similar percentage the involvement was bilateral.

Histopathologically the carcinoma was of the squamous-cell type in 33 cases, the basal-cell type in 1 case and the intraepithelial type in 1 case. In 8 cases the histologic nature was unknown.

The patients were given varied types of treatment. Based on the results obtained and from a study of the literature, the author proposes different procedures for the various clinical stages of penile carcinoma as follows:

1. If the lesion is less than 2 cm. in diameter, medium voltage roentgen therapy with a total tumor dose of from 4,000 to 6,000 roentgens or a radium mold delivering 6,000 roentgens (gamma) is recommended.

2. If ulceration with infiltration is present, the primary lesion is treated with a radium mold and deep roentgen therapy of a total dose of from 1,800 to 2,400 roentgens is administered over each groin.

3. If the corpora cavernosa are involved, penilectomy and bilaterally inguinal node dissection are performed associated with preoperative and postoperative deep roentgen therapy over the inguinal areas with a dose of from 1,800 to 2,400 roentgens on each occasion.

4. If the inguinal nodes are involved but not fixed, penilectomy, orchiectomy, resection of the scrotum and bilateral inguinal node dissection are done preceded by deep roentgen therapy or radium pack therapy to the inguinal regions and followed by deep roentgen therapy to the perineum in a dose of from 1,800 to 2,400 roentgens.

5. If the inguinal nodes are fixed and in recurrences, radium pack therapy is used.

In trying to tabulate the final results, the author was able to collect the follow-up data of only 10 patients. Of these 7 were alive and free of disease, 5 were alive with disease and 7 were dead. Of the 7 patients who were alive without disease, all had been treated by a combination of surgery and irradiation.

Radiation Therapy of Hodgkin's Disease (Zur Strahlenbehandlung des Lymphogranuloms). WILHELM TESCHENDORF. *Deut. med. Wochschr.* 1948 73 164

There is general agreement that effective roentgen therapy of Hodgkin's disease should cause the disappearance of all palpable glands and gland groups. The experience that gland regions subjected to heavy dosage are not soon reinvolved has led to the scheme of focal destruction. A dosage of from 2,000 to 4,000 roentgens given over a period of from 4 to 5 weeks will accomplish this. Many radiologists believe that one should then wait and employ radiation therapy again when new glandular masses appear. The question arises whether or not it is possible to hinder or eliminate the new development

of glands by properly timed radiation. Since one cannot predict the site of recurrence the question of total body radiation, or at least radiation of the entire trunk, must be considered. The author's method of total body radiation as used in leucemia was unsatisfactory in the management of Hodgkin's disease because of the severe general reaction which followed. His method of combining intensive local therapy with deep regional radiation of parts of the body in effect, total body radiation is described.

After intensive radiation of involved gland regions through local fields has brought about regression of the glandular masses, a short pause is prescribed. Residues often disappear only under further treatment. The body is then divided into four regions—breast, abdomen, upper back down to the diaphragm and lower back—and regional deep therapy of the entire body is begun. A dosage of from 25 to 50 roentgens per sitting from a distance of 100 to 160 cm. has proved adequate. Within a month the four regions are each radiated once either in four sittings in a week followed by a 3 week pause, or what is more comfortable to the patient in weekly treatments of one body region. Treatment is carried out for at least 10 to 12 months and repeated after a 3 to 3 month pause.

This scheme is only theoretically feasible and must be modified to suit the individual patient in accordance with his general condition and particularly with respect to his blood picture. It may also be necessary to interrupt the regional irradiation in order to carry out intensive local treatment of newly appearing gland enlargements.

Protocols of the management of 3 cases are given to illustrate the rhythm of the method.

RADIUM

The Treatment of Cancer of the Maxillary Antrum by Radium. MARGARET C. TOD. *Brit J Radiol* 948 70

Of the 222 patients with cancer of the maxillary antrum treated at the Holt Radium Institute of Manchester England from 1932 to 1941 25 per cent survived 5 years, most of them without evidence of recurrent disease. Those cases in which it was estimated that the whole tumor could be encompassed in a sphere 4 cm. in diameter and in which any recognized bone destruction was limited to not more than two adjacent walls of the cavity, were classed as early. These numbered 95 and the 5 year survival rate was 36 per cent whereas in the 127 "late" cases the survival rate was only 17 per cent.

From 1932 to 1937 the usual method of treatment was rhinotomy with surgical excision of the main tumor mass followed by insertion into the cavity of a ball of sponge rubber containing at its center a radium tube. The usual dose calculated on the surface of the sponge was about 8,000 roentgens delivered in 10 days. The method showed fair success even in some of the advanced cases, but the im-

mediate postoperative mortality was 25 per cent, largely as a result of sepsis or hemorrhage.

Therefore a simpler method was used in a large number of patients treated in the latter half of the 10 year period and was found particularly applicable to common squamous cell carcinomas of the antrum. In the 63 cases so treated the 5 year survival rate, with almost no evidence of recurrence, was approximately the same as for the previous method, while the immediate postoperative risk was much reduced.

This simpler method is as follows: under intra-tracheal anesthesia and with pharyngeal pack in place a tube containing 25 mgm. of radium in 3 cm. length is introduced, usually through the Caldwell-Luc approach, into the center of the tumor mass and left there until an estimated dose of 8,000 to 10,000 roentgens has been given in 7 to 10 days at points 2 cm. from the central radium source. The radium tube is thinly covered with rubber and the end of this rubber covering protrudes through the hole made for insertion and is fastened there by a rubber covered stay suture placed through the full thickness of the cheek.

Necrosis of any tumor tissue or even any normal tissue within the 2 cm. radius is the calculated result. No severe symptoms follow provided there is good drainage into the mouth through the hole in the antrum made for insertion of the radium. Occasionally if the tumor is large or if sequestering bone should hinder drainage the opening may have to be enlarged to clear out the slough. Pain is then promptly relieved. Penicillin of course, has proved useful in reducing sepsis.

The method is not recommended for tumors of the mixed salivary type or for those of the reticulo-endothelial type. The former group is very radio-resistant and therefore best treated by surgical excision. This was usually followed by radium, but little evidence was obtained that the radiation reduced the marked tendency of this type of slow growing tumor to local recurrence. Of 10 patients treated by the combined method 8 were alive 5 years later, but all except 3 showed recurrence.

The reticuloendothelial tumors are both sufficiently radiosensitive and infiltrative to make roentgen-ray over large fields extending from orbital ridge to clavicle the method of choice. A dose of 3,000 roentgens in 3 weeks is recommended. Of 18 patients with lymphosarcoma most of whom were treated by roentgen rays 50 per cent were living and apparently well 5 years later.

Biopsy for the ascertainment of cell type is therefore strongly recommended before final decision is taken as to method of treatment for any given antral cancer.

LILIAN DOUGLASS M.D.

MISCELLANEOUS

Effects of Small Daily Doses of Fast Neutrons on Mice. TITUS C. EVANS. *Radiology* 948, 50: 81.

The irradiation with neutrons in certain respects is more dangerous than the irradiation with roentgens

rays or radium. The maximum permissible daily exposure for roentgen rays and radium was set for some time at 0.1 roentgen per 8 hour day for a 55 day week. It is now necessary to establish a similar safe tolerance dose for the neutron rays.

With this view in mind the author has carried out a series of experiments on the effect of small daily doses of fast neutrons on mice. The work has been performed for the Manhattan Project and The Atomic Energy Commission.

In the preliminary experiments male and female mice of the Swiss Strain (Rockland Farms) were used. In the main experiments mice of the CF₁ strain (Carworth Farms) were also employed. The animals were from 4 to 6 weeks of age.

The neutron radiation was obtained from the 36-inch cyclotron in the Pupin Laboratories of Columbia University.

The dose was expressed in the arbitrary unit of "N" which represents the ionization produced in the 25 roentgen Victoreen chamber. It should be mentioned that the unit "N" used by other workers is based on ionization in a 100 roentgen Victoreen chamber, a fact which may account for considerable difference. The highest neutron intensity used by the author in his experiments was 1 "N" per minute.

The animals were irradiated in cages holding 25 mice each. Two cages were, as a rule placed together in a large semicircular lead box which was at a distance of 28 inches from the source.

The roentgen exposures were carried out with the following factors: 185 kv (peak) 2 mm. of copper and 1 mm. of aluminum as filters, 56 cm distance, field of 10 cm in diameter and an intensity of 10 r/min. The radiation was measured in air with the

same 25 roentgen Victoreen chamber as was used for measurement of the neutron rays.

The following summary of the results is given by the author.

Daily doses of 0.014 "N" of fast neutrons (0.07 "N" /wk.) equivalent to 0.1 r/day of x rays (on the basis of relative effects of single exposures) had no definite effect on mice treated for approximately 87 weeks.

Some effects (though still not pronounced) were observed in animals exposed daily to 0.07 "N" with a total dose of approximately 30 "N".

Daily exposures of 0.14 "N" (total of 60 "N") definitely reduced the survival time, slightly reduced the growth activity of the hemopoietic organs and gonads and slightly increased the frequency of cataracts.

Doses of 1.4 "N" per day resulted in death of more than 50 per cent of the animals by about the 29th week (total "N" = approximately 200). This irradiation caused pronounced changes within a few weeks in the blood counts and the activity of the hemopoietic organs and gonads. In addition extreme damage to the lens was evident by the time half of the original number of animals had died.

Daily exposures of 1.4 "N" were more effective than those of 11 roentgens (equivalents on the basis of relative effects of single exposures). Some effects based on the total dose at the time of appearance indicated a ratio of 12-13 roentgens to 1 "N". The effects of 1.4 "N" per day on the gonads and lens were more pronounced than even the ratio of 12 roentgens to 1 "N" would indicate.

Considering the results generally, the most important finding was that the lens was especially sensitive to the neutron radiation. T. LEUCURIA, M.D.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Streptomycin Dermatitis in Nurses. JOHN CROFTON and H. M. FOREMAN *Brit. M. J.* 948, 7

Four nurses of approximately 80 handling streptomycin at the Brompton Hospital, London, during a period of 8 months developed dermatitis. Their exposure varied from 6 weeks to 6 months.

The dermatitis consisted of an itchy papular erythema of the skin around the eyes and over the elbow flexures. In only one nurse were the hands involved.

Skin-sensitivity tests with 50 mgm of streptomycin in 0.1 ml. of saline solution were positive in the 4 affected nurses but negative in controls.

People handling streptomycin should wear rubber gloves and avoid soiling their skin with the material.

JOHN J. MALONEY M.D.

Metabolic Study of Burn Cases. J. W. KLYMER I S 5 948, 605

This work had as its principal object a complete study of the nitrogen balance of burned patients including the loss of protein in the exudation from the burned area. The report is divided into sections.

Urine was collected in bottles and chloroform, 0.5 per cent solution of this in chloroform was used as a preservative.

The total nitrogen in the urine was determined by the Kjeldahl method. The feces were usually not tested the fecal nitrogen generally being taken one-ninth of that in the urine.

The exudate was collected in cellulose or wool, the dressings being covered with washed sterilized cellophane placed immediately under the crepe pressure bandages to minimize leakage. The nitrogen in the dressings was determined by boiling them with 10 per cent sulfuric acid and taking a sample of mixture for Kjeldahl digestion. A blank value for dressings and reagents was obtained by treating in the same way an approximately equal quantity of the materials employed. The results were further corrected for the nitrogen in the penicillin-sulfathiazole cream used, it being assumed, for purposes of calculation that little or none of the sulfathiazole had been absorbed.

A fraction usually one fifth of the food was kept aside and at the end of the balance period was ground to a uniform paste. A portion of this, e.g. from 50 to 100 gm. was heated on a water bath with a little sulfuric acid for several hours and samples of the resulting solution or fine suspension were taken for Kjeldahl analysis.

Vomit was homogenized in the same way as food and a portion taken for analysis.

Plasma protein was estimated by the microdigestion and nesslerization method of King.

Urinary creatinine and creatine were determined by Folin's method.

Plasma chloride was determined on 0.5 or 0.1 ml. by digestion with silver nitrate in nitric acid and back titration with alcoholic potassium thiocyanate after the addition of alcohol. Blood was collected under liquid paraffin and the plasma separated as soon as possible.

Urine chloride was determined by the Volhard method.

Blood sugar was estimated by the method of Folin and Wu adapted for 0.1 ml.

Calculation of the areas burned was done by the surgeon and was based on Berkow's values.

RESULTS

Urinary nitrogen excretion. The urinary nitrogen excretion was measured in 30 cases, in 7 of which nitrogen balances were carried out. The cases are arranged in four arbitrary groups, as in the Glasgow Burns Unit report (L. Colebrook *et al.* 1944) viz—

Group 1 1-5 per cent of body surface burned.

Group 2 6-15 per cent of body surface burned.

Group 3 16-30 per cent of body surface burned.

Group 4 over 30 per cent of body surface burned.

It will be seen that few of the urinary nitrogen figures in Groups 1 and 2 are excessive and that some are in fact low. The highest nitrogen output observed was in a man of 23 years with 20 per cent burns who excreted 40 gm. of nitrogen in a 27-hour collection of urine beginning 3 days after the burning. This high loss of nitrogen in the urine was not maintained however, and his average daily excretion over a number of days, although above the normal amount, was not as high as might be expected. A boy of 17 years with 60 per cent burns excreted small amounts of nitrogen in the urine during the 4-5 days he lived. Some kidney damage was found at autopsy and this was confirmed by histological examination. This patient received methionine by mouth 2 days after admission but it is impossible to say what effect it had.

Nitrogen balances. Sixteen nitrogen balances were carried out in 7 cases of burns covering from 6 to 50 per cent of the body surface. Detailed case notes are given and these are followed by a discussion of the findings. Unfortunately it was impracticable to weigh any of the patients as the necessary apparatus was unobtainable at the time.

A distinction is made between the nitrogen taken in the food and that of intravenous plasma, and, where possible, between urine nitrogen and excreted nitrogen. In the experience of Major J. A. F. Stevenson, plasma given intravenously does not immediately increase the urine nitrogen. It appears to be simply added to the pool of body protein. This means that in nitrogen balance experiments in burns there are two things to consider—

a The total nitrogen balance over a period including any plasma protein lost in the exudate and protein given intravenously

b The metabolic state of the patient on a particular day or over a period of time (metabolic nitrogen balance) in calculating which intravenous plasma and protein lost in the exudate should probably not be included.

It appears that negative nitrogen balances in these cases were due to low intake rather than to a high output of nitrogen, and that when it was possible to induce the patients to eat well it was not very difficult to get them into nitrogen equilibrium. Taylor *et al* and Co Tui *et al* have shown that there is a marked tendency for burned patients to get into negative nitrogen balance, and Co Tui has drawn attention to five possible sources of nitrogen loss: (1) intratissue loss into the burned areas (2) loss in the exudate (3) hemoglobinuria (4) reduction in caloric and nitrogen intake as a result of anorexia and (5) the possible loss due to an antianabolic period, probably a result of altered hormonal balance. While it must be admitted that the loss in the exudate can be very large we would draw attention to the fact that this loss, as well as the intratissue loss referred to in (1), is largely compensated (so far as total nitrogen balance is concerned) by the plasma transfusions. Proteinuria was encountered in most, and hemoglobinuria in some of the severely burned patients, but the total amount of protein lost in this way was not large. With regard to the fifth source of loss, the urinary nitrogen was usually found to be not markedly above the normal and in fact some of these patients, especially women, excreted subnormal amounts of nitrogen in the urine. These findings are in agreement with the statement of Cope *et al* that extensive deep burns are not necessarily accompanied by a large loss of nitrogen in the urine. Cope *et al* attributed negative nitrogen balances in their cases to low caloric and nitrogen intakes and the low excretion of nitrogen to the relative absence of infection. Most of the author's cases were relatively free from infection.

It seems likely that the nutritional state of the patient is at least as important as the extent of the injury in determining the level of nitrogen excretion and it is possible that this may explain to some extent, why the author has not been able to confirm in all cases the large increases in urinary nitrogen output found by some of the American workers.

Note on food. Eggs and milk were used extensively and together contributed the greater part of the nitrogen and caloric intake of most of the balance cases. It is doubtful whether hydrolysates are indicated except when digestion or absorption is impaired or when it is impossible to ingest sufficient protein in a more palatable form.

Supplements of glucose were given.

It may be that protein and essential amino acids considerably in excess of the amounts adequate for the maintenance of nitrogen balance are required for healing but we have no exact data bearing on this.

The nitrogen in the exudate was measured in 7 other cases in which complete balances were not carried out.

Pressure dressings to minimize the loss of exudate from the burned area were used by Cope and Rhineland and by Koch, in America, and were investigated experimentally by Cameron *et al*. Mr J McK. Duncan of the Unit has used pressure dressings in an attempt to control exudation but there are no data demonstrating their effectiveness.

A quantity of blister fluid from a female with blister burns of the right hand and forearm was analyzed and the results were as follows:

Total nitrogen	0.56 gm. per 100 ml
Total protein	3.4 gm. per 100 ml
Albumin/globulin	1:6
Chloride (NaCl)	490 mgm. per 100 ml

It should be noted that as the clot of fibrin had already separated the figure for total protein will be slightly low and that for the albumin/globulin ratio slightly high.

In the second case that of a male aged 54 years, blister fluid (after separation of the fibrin) was found to contain 5.1 gm of protein per 100 ml the albumin globulin ratio being 3:3. The plasma protein in this case was 6.7 gm per 100 ml and the plasma albumin globulin ratio 1 to 9.

PLASMA PROTEINS

In 2 of the balance cases serial plasma protein determinations were made over several days. A less steep fall in the plasma proteins was found in one case that of a man of 58 years with burns involving the face, right arm and shoulder and left forearm and hands, he was not given a transfusion. It is possible that the steep fall in plasma protein was partly due to dilution with the transfused reconstituted plasma, which contained only 5 gm. of protein per 100 ml. In other burn cases low values were found.

CREATININE AND CREATINE EXCRETION

The urinary excretion of creatinine and creatine as compared with total nitrogen is shown graphically. The high output of nitrogen on the third and fourth day in a man with a 20 per cent burn was associated with a high output of creatinine (2.75 gm) and creatine (1.55 gm). Creatine was found in the urine of 2 other adult males with 15 per cent and 7 per cent burns respectively, but it was absent or present only in small amounts in the urine of 4 other adult males with burns of not more than 3 1/4 per cent. In some cases of creatinuria, in females as well as in males, there appeared to be a peak from the second to the fourth day but this may have been fortuitous.

Creatinuria has been reported as occurring in normal healthy males but other workers in extended studies have failed to confirm this. In certain of the author's cases it would seem likely that the creatinuria was to some extent a result of the injury and associated pyrexia.

It has been shown that the ingestion of readily assimilable carbohydrate is associated with creatin

therapy as an adjunct pressure dressings being used for immobilization.

The diagnosis is usually simple, but occasional cases with perianal fistulas of dermoid origin must be differentiated from true anal fistulas. The finding of hair in a fistulous tract is evidence of the dermoid origin of the disease. A sign to which the author attaches great significance is one of anal palpation in true anal fistulas one feels a fibrous tunnel or indurated cord from the border of the anus into the rectum in fistulas of dermoid origin situated near the anus, digital palpation does not reveal the fibrous tunnel in the anus as the latter has normal tissue elasticity but reveals the swelling of the fistula outside of the anus. Anoscopy injection of hydrogen peroxide or dyes into the tract and probing of the fistula also aid when the differential diagnosis is difficult. However the author describes 2 cases of concomitant true anal fistula and perianal fistula of dermoid-cyst origin.

The author describes a closed method of treatment of these cysts, using a plastic technique based on a geometric scheme. This method is applicable to the simple cysts and to the very complex ones with multiple fistulas as well. All the incisions are first traced out these include a rhombus encircling the fistula a superior and an inferior triangle for relaxation purposes and débridement incisions when necessary in the more complicated cases. The rhombus is traced out to include the cyst and fistula (Fig. 1). The superior triangle always with a height of 6 cm. is erected 1 cm. from the superior end of the rhombus, or lozenge-shaped figure, with a base measuring one-third of the longitude of the rhombus it is directed laterally and superiorly and extends to the gluteus muscle. The inferior triangle is constructed in a similar fashion on the opposite side from the superior it is directed laterally and inferiorly and extends to the depth of the fat of the ischio-rectal fossa. The outlined tissues are resected and the incisions are then closed with cotton sutures to leave a short central linear scar and two oblique lateral ones. In the complicated cases the triangles are drawn to fit the particular situation and closure is likewise effected either totally or partially. A large pressure dressing is used, held on by adhesive tape. Many of the patients are sent home immediately after the operation while others are kept in the hospital. The latter usually receive penicillin. Firm healing is usually complete in from 4 to 6 weeks.

The technique employed in several complicated cases with multiple fistulas is shown by several illustrations.

JAMES E. THOMPSON M.D.

Occult Bone Metastases. RALPH SHACKMAN and C. V. HARRISON. *Brit J Surg* 1948, 35 385

This study demonstrates how extensive bony metastases may be without there being any demonstrable radiological abnormality. Careful examination of the skeleton at postmortem has shown that metastatic tumor tissue may fill the marrow spaces and yet leave the bony architecture unaltered. The authors

Fig. 1 (Calzaretto) Superior triangulation, the base of the triangle is equal to one-third of the longitude of the rhombus (in this case 3 cm. and the height, 6 cm.). The inferior triangulation is constructed in accordance with the same rules.

took specimens of bone at autopsies on patients dead of malignant disease and selected those specimens which showed deposits discernible to the naked eye without apparent bony change.

Direct contact roentgenographs were made from these excised bones and macroscopically visible and radiologically invisible metastases were demonstrated in more than half of the cases examined. Color photographs are presented side by side with contact roentgenographs of the same bony parts showing the grossly visible metastases in the former and the absence of evidence of metastases in the latter. It is concluded that so-called normal roentgenographs cannot exclude the presence of even extensive bony metastases.

JOHN L. LUNDQUIST M.D.

Special Methods for the Diagnosis of Tumors in the Laboratory. N. CHANDLER FOOT. *Am J M Sc* 1948, 215 479

In spite of the development of newer methods for the laboratory diagnosis of tumors we are still quite dependent on the gross and microscopic examination of tumors. Papanicolaou has given great impetus to the diagnosis of tumors by smears. The success of this method is largely dependent on the cytological skill of the pathologist. The method has been used with success on vaginal fluids, fluids obtained by intrauterine aspiration, menstrual fluids, urine (for carcinoma of the bladder), sputum, and bronchial washings. Alimentary tract smears are not very successful because of the distortion of cells by digestion and because of the presence of many foreign cells from ingested meat and the like.

Aspiration biopsies fall into two classes: aspirated serous fluids and solid matter aspirated through a needle or cannula attached to a syringe. The author reports 85 per cent accuracy in diagnosis of aspirated fluids in his laboratory. The chief difficulty with this method is the confusion engendered by the presence of mesothelial cells which interestingly continue to divide in serous effusions much as in tissue culture. The 'needle biopsy' has been used quite generally for a long time, but there are serious disadvantages to this method. It does not give one sufficient evidence as to the topography of a given tumor and it may only produce an excellent smear of blood even though a tumor is present—particularly if the growth is fibrous. Much of the success of the ordinary tissue biopsy depends on the surgeon. He must be very careful in what he selects for examination. Frozen sections are very difficult to manage on tiny or feathery growths. Uterine curettings, unless very bulky, are also very difficult to manage by the use of this technique.

The author describes a case in which he was even asked to make a frozen section of a bony tumor. Special stain, tissue culture and examination of the blood and urine for certain chemicals are other modern supplements to tumor diagnosis.

JAMES HEAVY, M.D.

Pigmented Precancerous and Cancerous Changes in the Skin. V. K. K. OLKAR (*Ann. Res.* 1947, 1, 109)

The author reports the cases of 15 patients with pigmented Bowen's disease, squamous-cell carcinoma and basal-cell carcinoma of the skin seen at the Tata Memorial Hospital, Bombay, India, during the past 5 years. The importance of differentiating these tumors from the melanoma group is stressed.

Eleven patients presented single pigmented basal-cell carcinomas, most of them starting in pigmented moles and characterized by an insidious onset and slow clinical course. There was no deep infiltration or metastasis in all of the lesions were eradicated by excision or contact radiation therapy. Two patients with multiple pigmented basal-cell carcinomas were studied. Their lesions showed a clinical resemblance to pigmented nevi with no accompanying bands in the dermis; they grew slowly, did not metastasize, probably originated in pigmented moles, and exhibited variation in form, color and histological detail in the same person. Two more patients were presented who developed Bowenoid changes in the epidermis antecedent to a squamous-cell proliferation and the formation of typical squamous-cell carcinoma. In these 3 patients the lesion started as black patches and the growing peripheral areas were deeply pig-

mented as the result of proliferation of dendritic melanoblasts, while the overgrowth of neoplastic epithelial cells caused the central portion to become colorless.

The pigment in these tumors gave the usual chemical reactions of melanin, was unevenly distributed in the lobes of the tumor tissue and was more densely deposited in the peripheral cords. It occurred as dust in the cytoplasm of the cells in the stratum germinatum and some tumor cells, as diffuse coloring in degenerating melanoblasts, as coarse grains in the dermis as clumps in the melanophores and as amorphous masses in cystic spaces of the tumor. There was proliferation of dendritic cells in advance of the epithelial cells in these tumors. Part of the dark color of these tumors could be attributed to the lack of normal elimination of dead epithelial cells.

In one of the single basal-cell tumors there was a tendency toward healing in the central portion, and in one of the cases with Bowenoid changes several of the lesions were healing in the center. Therefore it is suggested that Bowenoid changes should be interpreted as carcinoma with reservations. The possible modes of evolution and spread of these tumors are discussed.

DUCTLESS GLANDS

Effect of Folliculin on the Development of Embryonal Implants (*Infanzia della folliculina sullo sviluppo degli embrioni embrionali*) PRIMO ACCIARI, *T. med.* Milano, 1947, 33, 204.

Experiments on implants of fetal tissue are performed on albino rats belonging to a species in which the effect of folliculin on transplantable mammary fibroadenoma had been studied. Embryos 15 mm long were removed from the uterus through a low midline incision and the triturated tissue was injected with a tuberculin syringe into the right breast. The animals were given injections of 500 international units of crystalline folliculin in aqueous solution daily starting the day following implantation of the fetal tissue and continuing until the death of the animal. The experiments were performed on pregnant and nonpregnant rats. The animals were sacrificed from 231 to 517 days after the implantation.

The author concludes from his experiments that large doses of follicular hormone administered over a long period of time favor the nidation and progressive development of implanted embryonal tissue. For a certain period of time the tissues grew but later regression of the major portion of the embryoma was noticed. Pregnancy exhibited an inhibiting effect on the nidation and the progressive growth of the tissues.

GYNECOLOGY AND OBSTETRICS

VOLUME 88

FEBRUARY 1949

NUMBER

VAGINAL AND OVARIAN METASTASES FROM HYPERNEPHROMA

Report of Case and Review of Literature

KARL H MARTZLOFF M D F.A.C.S. and CHARLES H MANLOVE, M D
Portland Oregon

SO-CALLED hypernephroma of the kidney is no rarity and in itself would warrant no special comment. The following case of left renal hypernephroma however is reported because of several unusual aspects viz. (1) the first clinical symptom was vaginal bleeding from vaginal metastases (2) left ovarian metastasis occurred without demonstrable evidence of defeminization or virilization and (3) the patient lived $2\frac{1}{2}$ years after the onset of her original symptoms and represents the 23rd reported instance of this unusual complication (Fig 1).

No attempt will be made to discuss the debatable question of the histogenesis of the tumors which are generally included under the term hypernephroma. The tumor in our case described in more detail later has been so designated because its component cells were large clear pale well delineated structures which generally characterize this group of renal tumors.

CASE REPORT

Mrs. H. S. white aged 57 years primipara, was first seen December 3, 1945 and died December 12, 1947. Her family and personal history were irrelevant. Menstruation ceased in 1937 or 1938. No vaginal bleeding or unusual discharge occurred until

From the Departments of Surgery and Pathology, University of Oregon Medical School, and the Surgical and Pathological Services of the Good Samaritan Hospital.

the onset of the present illness July 15, 1945 when there occurred a spontaneous bright red vaginal discharge. No other symptoms were noted and the patient felt otherwise well. Diagnostic curettage was done on July 16, 1945. The result of the histologic study is not known. Panhysterectomy was performed August 17, 1945; the tubes and ovaries were reported to have been left *in situ*. At this time a small black growth present in the vagina was removed but no histologic study was recorded. A growth of similar appearance and in a similar location was again noticed and removed on October 15, 1945. The pathologist was reported to have been unable to make a definite diagnosis but he did not consider the microscopic picture indicative of cancer. During the entire interval the patient's vaginal bleeding continued in varying amount with episodes so severe that obvious anemia and weakness ensued. When first seen by one of us (K. H. M.) in December 1945 because of vaginal hemorrhage no noteworthy weight loss had occurred.

Physical examination was made December 3, 1945. In the vagina was found a marked accumulation of secretion and a hyperemia due to the presence of a large vaginal pack placed there several days previously by patient's former physician. Vaginal tenderness was so marked that observation was unsatisfactory. It could be seen however that the cervix uteri was absent. Three small discrete red nodules 2 to 5 millimeters in diameter could be fairly distinctly recognized in the left half of the vagina. One of these bled freely. Bimanual abdominovaginal and rectal examinations revealed the firm character of the previously noted nodules and confirmed the absence of the entire uterus.

At examination one week later the vaginal inflammation had markedly lessened and the previously

noted nodules were all bleeding. Careful visualization of the vagina was again difficult.

On December 26, 1945, following hospitalization, complete physical examination was unimportant except for palpation of a large, normally movable left kidney. The urine on this and repeated examinations showed blood. However, only one of the specimens was obtained by catheter.

On December 27, 1945, at speculum examination done under gas anesthesia, absence of the cervix was verified and four nodules were identified (Fig. 2) viz: (1) profusely bleeding one about 1 centimeter in diameter on the left posterior or posterolateral wall about 3 centimeters within the introitus; (2) smaller nodule on the right anterolateral wall near the introitus; (3) one on the right lateral wall midway between introitus and vault; (4) one on the left lateral wall near the introitus. All but one of these were excised with the endotherm unit for biopsy and the bases of all were coagulated. Recovery was uneventful. Intravenous pyelographic study now revealed not only left renal enlargement but moderate hydronephrosis, medial displacement of the ureter and distention of the inferior calyces sufficiently characteristic to warrant the diagnosis of a inferior pole renal tumor. Patient returned home to await the result of the microscopic examination of the paraffin sections and the decision as to the best method of treatment of the left kidney disease. Histologic study of the vaginal nodules revealed a bizarre picture for a growth located in the vagina, namely, the structure of so-called hypernephroma (Figs. 3 and 4).

The clinical impression was malignant nephroma of the inferior pole of the left kidney with vaginal metastases which were the source of serious vaginal hemorrhage.

The patient was seen again January 25, 1946. All previously described vaginal areas were healed and left intact except for the left posterolateral area (Fig. 2, area 1) near the introitus which felt indurated. In addition there was a previously unobserved small nodule (Fig. 2, area 5) possibly 1 centimeter in diameter in the left anterior vaginal fornix. This was dark blue in color, smooth surfaced, firm in consistency and movable. Previous observations were confirmed. X-ray study revealed no recognizable evidence of metastases in the thoracic cavity, thoracic cage, shoulder girdle, dorsolumbar spine or ilium. The dubious outlook was discussed with the patient's family who felt that nephrectomy should be recommended to the patient.

X-ray studies on February 11, 1946, again showed no metastases. An anterior strapentoneal nephrectomy through a long left semilunar line incision was done on February 12, 1946. The left kidney with its tumor (hypernephroma) together with tumor tissue surrounding the ureter near the hilum and a segment of adjacent oviduct (verified histologically) posterior peritoneum was removed without event despite the adherence and marked vascularity of the tissues about the tumor. The entire exposure particularly the access to the renal pedicle under direct

vision and without undue mobilization proved essentially ideal with this approach. Recovery was uneventful, the patient was ambulant on the fourth postoperative day and on February 19, 1946, the nodule in the left anterolateral vaginal fornix was removed. This growth was histologically similar to the others. The operative wound was electrocoagulated and the area on the left posterolateral wall again coagulated. Recovery was uneventful.

Abdominal examination April 24, 1946, revealed no pertinent data. Speculum examination showed a small flat red area in the left fornix and a pinpoint red tumefaction possibly 1 centimeter in diameter on the left posterolateral aspect of the introitus (Fig. 2, area 6). This bled readily following slight trauma and was excised (May 7, 1946) with a wide margin of normal tissue. The base of this wound and the area in the left fornix were coagulated. The excised tumor was histologically similar to the others. Recovery was uneventful.

July 10, 1946, a mass was palpated in the left pelvis. Patient felt well and was doing her housework at this time. Previous abdominopelvic examination had been done January 23, 1946. The mass was firmly elastic, smooth, and rather freely movable with the vaginal vault. This observation was confirmed on September 12, 1946, although the mass had enlarged somewhat, now measuring possibly 8 to 10 centimeters in diameter. Examination was otherwise negative as were x-ray studies for metastases on September 11. The mass was considered ovarian in origin. The possibility that it might represent a manifestation of tumor metastasis was regarded as an obvious possibility. Laparotomy was done on October 1, 1946. The condition of the right tube and ovary was normal. The uterus was absent and the peritoneal surfaces, except for a few adhesions, appeared normal. A left-sided retroperitoneal mass attached to the left infundibulopelvic ligament and occupying the customary position of a retroperitoneal ovarian tumor was removed (though difficult). Histologically this mass proved to be similar in structure to the original renal neoplasm. Bleeding from the uterus on the postoperative pelvic wound was a serious complicating factor causing profound shock. Bleeding was completely controlled and closure was done without drainage. Palpation and inspection in the general region of the previously removed left kidney disclosed nothing pertinent but of other exploration was done because of the blood loss. Patient left hospital on the 12th postoperative day and was again subjectively well.

December 16, 1946, a nodule (Fig. 2, area 7) 4 millimeters in diameter was noted on right anterior vaginal wall, in the introitus 1 centimeter from the external urethral meatus. This had a pink base and purplish apex (Fig. 1). It was smooth, firm, fixed to the mucous membrane but movable over the underlying structures and was excised with an endotherm unit January 28, 1947. The specimen measured 1.2 by 0.8 by 0.2 centimeter. The patient has last been seen in April 1947, showed possible evidence of recurrence.

Fig 1 Metastatic hypernephroma nodule on right vestibulum vaginae. This was last vaginal nodule observed and excised. Figure 2 spot 7 represents this tumor

Fig 2 Diagrammatic representation of location of vaginal hypernephroma metastases. Nodules 1 to 4 were observed December 27 1945 nodule 5 January 25 1946 nodule 6 (possibly remanifestation of nodule 2) April 24 1946 nodule 7 December 16, 1946

She felt weak and appeared ill but without definite weight loss. Palpation revealed a definite sense of fullness in the left flank. The blood sedimentation rate was 49 millimeters in 45 minutes in May 1946 and continued moderately but definitely accelerated. She subsequently developed a hemiplegia and a definitely palpable mass was noted in the left flank. She died December 12 1947 29 months from the time of the first symptom—vaginal bleeding.

Gross examination of the specimen. The metastatic vaginal nodules for purposes of brevity will not be described in detail. Their cut surfaces were firm and showed gray and white striations. Some areas showed rather large blood containing channels.

The left kidney (Fig 9) in its fixed state measured 15 by 8.5 by 7 centimeters. The surface was rough and its inferior half was occupied by a somewhat nodular enlargement which appeared everywhere encapsulated except at a point on its medial aspect where the capsule was broken. On section the pelvis showed obvious though moderate hydronephrosis and in its inferior portion distortion by the tumor. The sectioned tumor surface appeared gelatinoid with areas of softening and hemorrhage and was generally of a light yellowish color with areas of deeper yellow and elsewhere areas that were light brown.

The renal vein on careful dissection showed no demonstrable tumor invasion. The left pelvic tumor was a round well encapsulated mass which in its fixed state measured 6.3 centimeters in diameter. In

cross section there was a central zone of softened liquefying pink material. The more solid, though spongy peripheral portions showed a yellowish coloration with radiating red and pink striations. There was a capsule about 2 millimeters thick. The fallopian tube could not be definitely recognized in the gross though its presence was verified histologically.

Histology. The histology of all the tumor tissue was similar to that of the renal tumor which has been described. This was composed of large compact alveoli filled with large polyhedral cells with distinct cell outlines. The cytoplasm was abundant, generally clear but often contained some fine pink staining particles. The nuclei were generally round and varied moderately but definitely in size and staining reaction. The chromatin was moderately to coarsely granular stained deeply and lay in a comparatively pale blue to clear nuclear matrix. Nucleoli were almost uniformly present. Mitoses were infrequent. The fibrous matrix comprising the supporting structure of the tumor was composed of fine strands of connective tissue varying from one to several cells in thickness. Blood vessels per se were practically absent.

There was a general tendency for central degeneration to occur in these cell masses so that some had the appearance of glandular alveoli. Many of these contained central areas of hemorrhage. Some were lined with a single layer of tumor cells without evidence of degenerative change. Here the alveolar space was occupied by normal appearing red blood

Fig. 3. Vaginal mucosa and underlying tumor. This represents spots 3, or 4 in Figure 1. Specimens are not separately labeled (time removal).

cells and had the appearance of a muscular channel. Viable tumor tissue was generally visible only at the periphery of the neoplasm elsewhere there was necrosis.

Fig. 4. High power from tumor area in Figure 3.

Fig. 5. Vaginal nodule showing tumor emboli in blood.

In fact necrosis was so general that blocks for good sections were difficult to obtain.

The vaginal metastases differed from the foregoing only in that overlying stratified vaginal epithelium was generally present. In some sections this was intact. In others there was overlying ulceration where the neoplasm had reached the surface. Tumor emboli could not generally be identified. However an occasional blood vessel (vein) was seen showing unmistakable tumor embolus (Figs. 5 and 6). Vascular spaces lined with a single layer of tumor cells, as previously described, were common and undoubtedly account for the profuse hemorrhage that occurred when the tumor ulcerated through the vaginal mucosa. They might also be the source of tumor cell emboli and might explain metastatic phenomena when invasion of renal vein was not demonstrable.

Sections of the left pelvic tumor differed only from the foregoing in that ovarian stroma with a corpus albicans (Fig. 7) and the fallopian tube showing tumor infiltration of its external muscularis are recognizable at the periphery of the tumor.

Autopsy findings which are given in barest outline revealed a left retroperitoneal tumor occupying site of previously removed left kidney and extending from lower pole of the spleen into left pelvis at apex of the vaginal vault. The vaginal mucosa is smooth and shows no tumor. The left adrenal gland lies in close apposition to the tumor mass but shows no neoplastic involvement. The inferior vena cava shows tumor which extends superiorly for 3 centimeters from site of the left renal vein.

Metastases are found in the right kidney cortex, spleen, lungs, brain and myocardium of the left posterior ventricle.

Fig. 6 High power of blood vessels with tumor emboli in Figure 5

DISCUSSION

The occurrence of hypernephromatoid structures in the vagina either as fetal rests or as metastatic phenomena from a malignant tumor of similar character is rare. Deming in a study of 29 patients with metastases from renal tumors reports no metastases to ovaries or vagina. Eleven of the tumors were hypernephromas and 5 were adenocarcinomas. In a review of 46 ectopic adrenal rests (not metastases) Lasher describes none occurring in the vagina. Likewise Nalle in a study of 58 renal neoplasms and their metastases encountered no vaginal or ovarian metastases.

Wynne states that about 20 instances of vaginal metastases from nephromas have been reported. Novak considers them extremely rare. Wharton describes two instances of vaginal metastases from renal tumor. In one of these the vaginal tumor which occurred in the vestibule was the first direct proof of the existence of renal tumor thereby simulating Gragert's case.

It is understandable that when metastases become widespread as in the 4 cases reported by Sharnoff and Sala vaginal metastases as late antemortem phenomena are probably not rare. No doubt they would be recognized more frequently if sought at autopsy.

Fig. 7 From left ovary Corpus albicans at A. Histology of tumor similar to that shown in Figures 3 and 8.

Most writers attribute to Henke the first reported case of vaginal metastases from a

Fig. 8 High power of tumor area in Figure 9.

hypernephroma. Sharnoff and Sala state that Henke's patient was 69 years old that autopsy showed hypernephroma of the left kidney and that in both the renal and vaginal tumors the histologic picture was identical. As a matter of fact, Henke's report is a fragmentary 11 line statement without illustrations and without detailed histologic description. It does not state which kidney was involved in the hypernephroma and it gives the patient's age as 60 years.

In all likelihood the case reported by Hoffmann is the same as the one reported by Henke although all writers have considered each of these as being separate. Henke's report as previously noted is brief fragmentary and gives no details. Hoffmann's report is complete and states that Henke examined the tissue from his case and reported his observations. Additionally in each instance the patient was 60 years of age and had a metastatic skin tumor which showed hypernephroma cells on biopsy. Hoffmann specifically states that this tumor was located in the right thigh and the renal tumor demonstrated at autopsy in the left kidney. There is little danger of error there fore in considering these two reports as concerning the same patient.

The case reported by Overy is also generally accepted by writers on this subject. Overy's case is reported in a discussion of a paper by Doran. He describes an instance of his own in which a patient with a right sided abdominal mass developed a polypoid tumor on the anterior vaginal wall. This tumor was removed, recurred and was again removed. No histologic studies were made of these tumor-factions. The patient died 1 month later and a hypernephroma was found at autopsy. Overy does not state on which side the tumor was located. It is difficult in the absence of histological verification to see how this case can be considered as an instance of vaginal metastasis from a hypernephroma.

Reference to Table I reveals that including our patient 23 instances of hypernephromatous vaginal metastases have been reported. As in our patient the overwhelming majority (18) have occurred in the presence of left renal tumors. This combination has raised some questions, namely are left sided tumors more

frequent than right sided ones? If left sided tumors show a predilection for vaginal metastases, what is the explanation? To answer the first question it may be said that malignant renal tumors in adults occur probably more frequently on the right side. Lubarsch states that 321 of Kuesters 607 collected cases of malignant renal tumors occurred on the right and 272 on the left while of 169 similar tumors collected by Albarran and Imbert 90 occurred on the right and 74 on the left side. Deming reports that among 82 malignant renal tumors studied 53 occurred on the right side. In this same study he found that men were afflicted about 2 5 times more frequently than women.

When malignant renal tumors are segregated according to histologic types all of Lubarsch's compilations for hypernephromas show that men are again more frequently affected than women in a general ratio of about 2 to 1. However when the side affected is considered there appears to be only a slight preponderance of lesions on the left side the general ratio being about 1 3 to 1.

Therefore if it is accepted that hypernephromas occur with possibly slightly greater frequency in the left kidney then it is not mere coincidence that the overwhelming preponderance of vaginal metastases occur only in the presence of left renal tumors.

The major constant circulatory difference between the two kidneys occurs in the communication of the left spermatic (ovarian) vein with the left renal vein and the comparative shortness of the right renal vein and left renal artery. In view of the well recognized tendency for hypernephromas to invade the renal veins, it seems a fair assumption that the left ovarian vein offers the avenue by which the ovarian involvement occurred in our patient and by which vaginal involvement occurs in the majority of reported instances.

The occasional reported instance of uterine involvement is also probably similarly explainable. The free anastomosis between the left ovarian vein the pampiniform plexus, the uterovaginal venous plexus and its more distal anastomoses as shown by Kowatzki and others, offers a logical explanation for the vaginal dissemination of the tumor in our case. The demonstration of venous tumor emboli in

the vaginal metastases in our patient offers support to this explanation as opposed to a possible lymphatic mode of spread which is espoused by some authors. The theory of implantation on the vaginal mucosa of tumor cells passed in the urine as suggested by Shar-noff possesses little if any corroborative evidence.

One cannot help but entertain the suspicion that if the theory is correct that the left spermatic (ovarian) vein offers the route for retrograde metastasis of hypernephroma to the vagina then it should follow logically that left testicular metastasis must occur with equal or possibly greater frequency in men afflicted with left sided hypernephroma and would be recognized if looked for.

According to this and similar studies hypernephroma metastases to the vagina may be considered as rare lesions. We suspect however that their rarity is overevaluated. Similar instances undoubtedly occur are recognized but are not reported. The 2 cases mentioned by Wharton illustrate this point.

All patients in this study with the exception of Cragert's patient Fleischmann's second case and our patient died within 24 months following the recognition of the vaginal lesion. Fleischmann's and Cragert's patients both deserve special comment. The diagnosis of hypernephromatoid tumor was made on biopsy of the vaginal tumor of Cragert's patient. However it was not definitely determined whether this represented a benign or a malignant process. The patient was seen again 16 months later with the story of having noted a left sided abdominal swelling for 6 months. Ixycographic studies were negative but left nephrectomy revealed a hypernephroma. The patient was living and well 4 months after the nephrectomy and 21 months from the time of the original biopsy of the vaginal tumor.

Fleischmann's second patient was seen January 9, 1918 for vaginal bleeding from a small ulcerated nodule which was removed from the left posterior vaginal wall. Definite diagnosis was not made from the biopsy and the lesion was considered as a possible adenoma carcinoma. Three months later a left lumbar tumor was discovered when patient was examined for left hypochondriac pain. Left neph-

Fig. 9. Longitudinal section of left kidney with inferior pole neoplasm. Tumor had perforated capsule at a and involved parietal peritoneum.

rectomy was done 5 months later following deep x-ray therapy and several new vaginal nodules were also removed. The renal tumor was a hypernephroma and the vaginal nodules were recognized as similar to the renal lesion. Intermittent x-ray therapy was given to local and remote remanifestations of the disease. Death occurred May 19, 34 years 8 months after the lesions were recognized as hypernephroma.

In view of the foregoing and since an occasional patient comes to autopsy and reveals no other metastases than the vaginal lesion as illustrated by Graefenberg's first case it appears justifiable to operate in such instances provided no other signs of metastases are demonstrable. Furthermore on the basis of the experiences of Cragert of Fleischmann in his second case of Graefenberg in his first case of Hirsch-Hoffmann and of our own experience one is led to the conclusion that in the absence

*Cases have been considered acceptable for tabulation if vaginal lesion showed histologic presence of hypernephroma although suspected kidney may not have been removed.

of any other conclusive signs and symptoms if a hypernephromatoid lesion is demonstrated in the vagina, one would be sufficiently certain in suspecting the presence of a left hypernephroma to warrant surgical exploration of the left kidney.

Radiation therapy as used in treating some of the patients reported in the literature covered by this study, with the possible exception of Fleischmann's patient, did not appear to be of material benefit.

Numerous authors place considerable stress on the apparent predilection of the hypernephromatous vaginal metastases to appear on the left anterior vaginal wall near the external urethral meatus and they are of the opinion that bleeding from this source may be the first sign of mischief. Reference to Table I reveals that of the 23 cases tabulated, 11 patients complained of vaginal bleeding as an original symptom, 8, however, apparently did not bleed and in 4 no statement is reported.

The anterior vaginal wall of the region near the external urethral meatus was the site of a

single primary metastatic tumor 12 times. This tumor appeared to the left of the midline in 8 instances, to the right in 1 and apparently at the midline in 3. Probably no further generalizations can be drawn other than, as pointed out by Taussig, tumors which metastasize to the vagina, presumably via the blood stream, often show a predilection for localization in the distal vagina and frequently in its anterior aspect near the external urethral meatus.

SUMMARY

A case is reported in which bleeding from vaginal metastases was the first symptom of an unsuspected left renal hypernephroma. The case presumably represents the 23rd instance of vaginal metastases complicating hypernephroma reported in the literature. The complication is generally limited to tumors of the left kidney, although exceptions are reported.

All patients with hypernephroma complicated with vaginal metastases whose ultimate outcome is known died as the result of the

ulcerated surfaces need, of course, to be removed. If marked inflammatory changes are present around the fistula or in the skin externally, operation should be postponed until the structures involved have been restored to a state as nearly normal as possible and with no evidence of active infection. As a part of the preoperative study the condition of the upper urinary tract is investigated always by intravenous pyelograms or ureter catheterization or both. In cases of active bladder infection, the latter may be withheld until the acute infectious process has subsided. It is important to determine the patency of the ureters and to learn whether or not they are dilated, and it is essential to know in advance of the operation the condition of the kidneys and their functional value. One of our patients had congenital polycystic disease. Two of our patients with vesicovaginal fistula had also a ureterovaginal fistula. In our experience the communication between the ureter and the vagina is always associated with complete ureteral stricture below this level and usually is accompanied by some dilatation and infection in the ureter and kidney above.

In some cases of vesicovaginal fistula in which there is danger of ureteral injury during the plastic repair, it is wise to place catheters within the ureters at the start of the operation. In certain difficult cases we have catheterized the fistula itself as an aid in the dissection. We have occasionally encountered a small fistula in the posterior lip of the internal sphincter margin or in the urethra just beyond that could not be found until a ureteral catheter was passed upward through the opening in the vagina below.

SUTURE MATERIAL

In 1834 Montague Gosset of London successfully closed a vesicovaginal fistula with gilded silver wire sutures. In 1849 J. Marion Sims closed Anarcha's vesicovaginal fistula with silver wire sutures at the thirtieth operation, having failed twenty nine times with all the suture material he had previously utilized. The great advantages of silver wire are that it causes no inflammatory reaction in the tissues and that it is said to repel infection. The disadvantages are that it has low tensile strength

it cannot be tied; it must be fixed by twisting, and it may produce a disfiguring local argyria. In recent times a metal rustless alloy steel wire has come into use. Primarily recommended by W. Wayne Babcock of Philadelphia for the suturing of septic wounds, and recommended by him in the closure of vesicovaginal fistulas, this alloy wire has all the advantages of silver wire and none of its drawbacks. It is soft, strong, nonirritating and does not discolor the tissues. The tensile strength is such that a very fine gauge suture may be used and a strong knot may readily be tied. A century ago when vesicovaginal fistulas were first closed, there was but one operative technique which consisted of paring the edges of the fistula and approximating them in one layer with sutures. It is obvious that metallic sutures by their strength and lack of irritation offered great advantages in that type of operation. With the development of surgical technique in general and of the operation for vesicovaginal fistula in particular, certain striking changes have occurred. Now days in the closure of difficult fistulas the bladder and the vagina are separated from each other and each structure is freely mobilized. Because of this dissection, the edges of the bladder and the vagina may be brought together without tension by fine suture material. Fine chromic catgut can be used successfully in this type of operation while the larger strands of catgut failed in the classical Sims procedure. A method that has frequently proved advantageous in our hands consists of closing the bladder with fine chromic catgut sutures avoiding the mucosa and of closing the vaginal wall with alloy wire or silver wire sutures. In our opinion, silk and cotton have no place in the management of these fistulas. When working through the vagina in closing a vesicovaginal fistula in layers it is important not to resect the edges of the vaginal wall before approximating them so as to avoid all tension, and to have sufficient vaginal wall with which to work should a recurrence develop requiring still another operation.

VARIETY OF OPERATIONS

On account of the great variety of vesicovaginal fistulas met in clinical practice nu

chromic catgut, depending upon the amount of scar tissue present. Great care is used in placing this first layer of sutures, which must accomplish complete approximation without tension. The defect in the bladder is now closed in one or two layers. When the thickness of its wall is adequate, the muscle alone is brought together with interrupted sutures of No. 00 chromic catgut after which the mucosa may be approximated with a continuous suture of double zero or triple zero chromic catgut. The bladder and vaginal suture lines may be planned when possible to lie in opposite directions but the bladder must be repaired always in a way that will result in a minimum of ureteral and urethral disturbance.

When the plastic procedure has been completed, the ureteral catheters are removed and the bladder is closed anteriorly with continuous fine plain catgut in two layers leaving a mushroom catheter, size 26 French in the upper pole of the incision for constant suprapubic drainage of urine. The catheter is irrigated gently with normal saline to be sure that it functions well. A small rubber tissue drain is placed on each side of the bladder to emerge through the prevesical space at the lower angle of the wound. The rectus muscles are approximated above and especially below the suprapubic catheter with interrupted sutures of fine plain catgut. The rectus fascia is closed with interrupted zero chromic catgut. Silk stay sutures may be used if desired. A suprapubic sinus thus formed will heal promptly when the drainage tube is removed. The stubborn sinuses are those which have been placed low in the bladder and just above the symphysis. The catheter should lie high in the wound and high in the bladder where it will produce no irritation near the plastic repair.

Sterile constant urinary drainage is maintained with meticulous care. Bladder distention must be avoided but irrigations are not used unless necessary. The best insurance against obstruction is a high fluid intake. Penicillin and sulfadiazine are given to combat infection. The drains in the prevesical space are removed usually in 4 or 5 days. The suprapubic catheter is taken out in 3 or 4 weeks and in most cases the patient is kept in bed during all of that time.

SUPRAPUBIC BLADDER DRAINAGE IN VESICOVAGINAL FISTULA

Drainage of the bladder through a suprapubic incision is a common urological procedure, but a review of the chapter on vesicovaginal fistula in most of the important text books of gynecology fails to show any mention of this method of diverting the urinary stream after operations for vesicovaginal fistula. Suprapubic drainage has been described as a part of the intravesical operation that we have presented. We wish to emphasize its advantage also in difficult cases of vaginal repair. We use it frequently and regard it as one of the most important advances that we have made in the management of this problem. Diversion of the urinary stream is of obvious benefit during the process of healing and the suprapubic tube affords more certain drainage than the urethral catheter. Properly placed, it will remain in position; it is less likely to become obstructed and it will not produce irritation in the region of repair. It is especially important in those cases in which the fistula involves the urethra. Suprapubic drainage adds but little to the difficulty and shock of the operation. It is established immediately following the vaginal procedure in many instances in our clinic. Healing seems more certain; the care of the perineum is more satisfactory and a well constructed suprapubic sinus never fails to close promptly in the presence of a normal bladder outlet. In the 40 cases of vesicovaginal fistula reported 13 patients 32.5 per cent had suprapubic drainage 4 after the intravesical operation and 9 after the vaginal procedure. We are convinced from our experience that the more common use of this method of drainage would lead to happier results in the management of difficult urinary fistulas.

SCHUCHARDT INCISION

Schuchardt's incision, also known as the paravaginal incision, was proposed in order to facilitate through better exposure, the radical vaginal operation for carcinoma of the cervix. It is also of great value in exposing a vesicovaginal fistula situated high in the vagina, especially that which follows a panhysterectomy and which is situated in a scarred retracted vaginal vault. It is usually performed on the

merous methods of closure have had to be devised. These may be summarized as follows:

1. The vaginal procedure including several varieties of technique.

A. Paring the edges and closing them in one layer with silver wire or alloy wire sutures.

B. Circumcising the fistulous opening turning a cuff into the bladder, closing the fistula by approximating the bladder musculature over the cuff without penetrating the bladder mucosa and closing the vaginal wall separately. The vaginal wall may be satisfactorily closed by means of metallic sutures placed perpendicularly to the line of bladder suture thus staggering the suture lines.

C. Mobilizing the bladder and closing the bladder and vagina in separate layers.

D. Using the cervix and body of the uterus to close the opening.

E. Suturing pedicled flaps from the vagina and vulva to bridge over the defect.

F. Using the gracilis muscle as a pedicle flap (Garlock technique).

G. Colpocleisis.

H. Partial colpocleisis—Latzko.

2. The intravesical procedure through a suprapubic incision (Phaneuf and Graves) described and illustrated herein.

3. The suprapubic extraperitoneal procedure through a Pfannenstiel incision.

4. The intraperitoneal procedure through an abdominal incision (Leguen technique).

5. Implantation of ureters in the sigmoid.

THE INTRAVESICAL CLOSURE OF VESICOVAGINAL FISTULA

It is a well known fact that almost all vesicovaginal fistulas may be closed by the vaginal approach. There are, however, a certain few vesicovaginal fistulas so situated that they cannot be seen or exposed through the vagina. It is for this small group of cases that we have devised a method of intravesical closure which we are describing and illustrating as follows.

Operative procedure. The Trendelenburg position is used. A midline suprapubic incision beginning low over the symphysis, exposes the extraperitoneal region of the bladder by separating the rectus muscles. Careful dissection of these muscles serves as a useful guide in approaching this region when normal

cleavage planes have been obliterated by the scar of a previous operation. Separation of the recti from their sheaths on each side along the line of incision also adds to the ease of retraction. The fat and fascia overlying the bladder are divided beneath the symphysis and the anterior peritoneal reflection is dissected gently upward to expose in its entirety the anterior vesical wall. The sides of the bladder are then separated from adjacent fat or scar as far downward as the region of the bladder neck. This free mobilization is very important and makes it possible to obtain a very satisfactory intravesical exposure of the area occupied by the fistula.

The bladder is opened in the anterior midline by an incision long enough and low enough to permit an adequate view of its cavity when a self retaining retractor has been placed in position. A curved ribbon or tongue-depressor retractor held against moist gauze in the dome of the bladder helps to draw the region of the trigone and the fistula upward into the field. Ureteral catheters usually of size 5 or 6 French, are now passed through the ureteral orifices to define the position of the ureters accurately during the operation. The internal orifice of the urethra is carefully observed and it also must be protected against injury. Silk traction sutures are placed in the bladder around the fistula, as shown by the artist, about 0.5 centimeter from the edge of the opening. These sutures held upward, one at a time by the operator or his assistant, help greatly in the subsequent dissection.

The margin of the fistula is incised around its circumference with a small No. 15 Bard Parker blade and the whole thickness of the bladder wall is carefully separated from the vagina in all directions. The separation is carried out widely enough to permit the final repair of these structures without tension. Care must be used to avoid the ureters and further vaginal injury. In one difficult case, in which the fistula lay close to the outlet of the bladder the operator placed fingers of the left hand in the vagina to guide the dissection which in this region must preserve the urethral musculature. When bladder and vagina have been well mobilized the vaginal opening is closed with interrupted sutures of No. 0 or No. 00

chromic catgut, depending upon the amount of scar tissue present. Great care is used in placing this first layer of sutures which must accomplish complete approximation without tension. The defect in the bladder is now closed in one or two layers. When the thickness of its wall is adequate the muscle alone is brought together with interrupted sutures of No. 00 chromic catgut, after which the mucosa may be approximated with a continuous suture of double zero or triple zero chromic catgut. The bladder and vaginal suture lines may be planned when possible to lie in opposite directions but the bladder must be repaired always in a way that will result in a minimum of ureteral and urethral disturbance.

When the plastic procedure has been completed the ureteral catheters are removed and the bladder is closed anteriorly with continuous fine plain catgut in two layers leaving a mushroom catheter size 26 French in the upper pole of the incision for constant suprapubic drainage of urine. The catheter is irrigated gently with normal saline to be sure that it functions well. A small rubber tissue drain is placed on each side of the bladder to emerge through the prevesical space at the lower angle of the wound. The rectus muscles are approximated above and especially below the suprapubic catheter with interrupted sutures of fine plain catgut. The rectus fascia is closed with interrupted zero chromic catgut. Silk stay sutures may be used if desired. A suprapubic sinus thus formed will heal promptly when the drainage tube is removed. The stubborn sinuses are those which have been placed low in the bladder and just above the symphysis. The catheter should lie high in the wound and high in the bladder, where it will produce no irritation near the plastic repair.

Sterile constant urinary drainage is maintained with meticulous care. Bladder distention must be avoided but irrigations are not used unless necessary. The best insurance against obstruction is a high fluid intake. Penicillin and sulfadiazine are given to combat infection. The drains in the prevesical space are removed usually in 4 or 5 days. The suprapubic catheter is taken out in 3 or 4 weeks and in most cases the patient is kept in bed during all of that time.

SUPRAPUBIC BLADDER DRAINAGE IN VESICOVAGINAL FISTULA

Drainage of the bladder through a suprapubic incision is a common urological procedure but a review of the chapter on vesicovaginal fistula in most of the important text books of gynecology fails to show any mention of this method of diverting the urinary stream after operations for vesicovaginal fistula. Suprapubic drainage has been described as a part of the intravesical operation that we have presented. We wish to emphasize its advantage also in difficult cases of vaginal repair. We use it frequently and regard it as one of the most important advances that we have made in the management of this problem. Diversion of the urinary stream is of obvious benefit during the process of healing and the suprapubic tube affords more certain drainage than the urethral catheter. Properly placed, it will remain in position; it is less likely to become obstructed and it will not produce irritation in the region of repair. It is especially important in those cases in which the fistula involves the urethra. Suprapubic drainage adds but little to the difficulty and shock of the operation. It is established immediately following the vaginal procedure in many instances in our clinic. Healing seems more certain; the care of the penneum is more satisfactory and a well constructed suprapubic sinus never fails to close promptly in the presence of a normal bladder outlet. In the 40 cases of vesicovaginal fistula reported 13 patients 32.5 per cent had suprapubic drainage 4 after the intravesical operation and 9 after the vaginal procedure. We are convinced from our experience that the more common use of this method of drainage would lead to happier results in the management of difficult urinary fistulas.

SCHUCHARDT INCISION

Schuchardt's incision also known as the paravaginal incision was proposed in order to facilitate, through better exposure, the radical vaginal operation for carcinoma of the cervix. It is also of great value in exposing a vesicovaginal fistula situated high in the vagina, especially that which follows a panhysterectomy and which is situated in a scarred retracted vaginal vault. It is usually performed on the

left side, and the length of the incision is governed by the amount of room required. We have found this procedure to be extremely valuable. It was used in 11 of the 40 cases included in this study or in 27.5 per cent.

POSTOPERATIVE CARE

Regardless of the type of operation employed in cases of vesicovaginal fistula, the postoperative care is of vital importance. It requires close supervision preferably by the operator himself and it never should be delegated to inexperienced assistants. The primary consideration is the avoidance of bladder distention and infection during the period of healing. Every precaution must be taken to prevent interruption of catheter drainage. The suprapubic or urethral catheter must be maintained unobstructed and in good position. As has been stated we prefer suprapubic drainage in the difficult cases. Irrigations always gentle and without bladder distention are used as little as possible to minimize the risk of the introduction of fresh infection. Vigorous antiseptic solutions productive of irritation or discomfort, are unnecessary. Potassium permanganate solution is used most often in our cases. The best and safest irrigation is provided by an adequate fluid intake. It is not necessary to irrigate a catheter that is freely discharging clear urine. Until the patient is able to take by mouth and retain an average of 2500 to 3000 cubic centimeters of liquids each day parenteral fluids are essential. These will vary in amount and kind with the general state of the patient and her circulatory condition.

Infection in the bladder and vagina is always reduced to the minimum before surgery is undertaken in these cases. Bacteriological study of the urine is made at the time of the original examination and as often as indicated during the convalescence. The antiseptic program is based upon these cultures. Sulfadiazine is given usually a few days before operation 0.5 gram every 4 hours day and night, combined with sodium bicarbonate 1.0 gram and continued for several days after operation. When it is apparent that infection is well controlled these medicines may be given at 6 hour intervals and we omit them entirely in

most cases within 7 to 10 days after surgery to avoid occlusion of the catheter with alkaline deposits. For the remainder of the convalescence the patient receives methenamine and sodium biphosphate, 15 grains of each 4 times daily. Indwelling catheters become obstructed less quickly when the urine is acid. Penicillin is used as a rule for the first few days after operation until the temperature is normal and the wound is healing well. We resort to streptomycin whenever necessary. It is important to remember that this drug has been shown to be more effective in an alkaline urine.

Urethral catheters are removed as a rule in about 14 days. Suprapubic catheters are allowed to remain for 3 to 4 weeks. When metallic sutures have been resorted to in closing the vagina they are removed at the end of 4 weeks always under anesthesia. Intravenous anesthesia serves a useful purpose in this connection but general anesthesia may be employed if preferred. The patient is permitted to get out of bed the day after the drainage apparatus is removed. When urethral drainage is employed she may be allowed to go home on the 15th postoperative day to return to the hospital in 2 weeks or in 1 month from the time of the operation to have the metallic sutures removed, if wire has been used.

URETEROINTESTINAL ANASTOMOSIS FOR IRREPARABLE FISTULAS

An occasional case of vesicovaginal fistula is encountered in which there seems to be little likelihood of achieving urinary control by any of the described procedures. In such cases it is desirable in some instances, to resort to transplantation of the ureters to the large bowel. The most common reasons for this operation are first destruction of the bladder sphincter which will render the patient still incontinent, even though the fistula be repaired, and second, necrosis leading to fistula as a result of irradiation. Ischemia, produced by radium or x ray with endarteritis and fibrosis around the periphery of a fistula, does not present a favorable field for plastic surgery.

There have been 6 patients in this series who have had ureterointestinal anastomoses. Two had urethrovaginal fistulas with severe urethral injury and loss of the sphincter mus-

Fig 1. Artist's drawing. a, Median suprapubic incision between the symphysis and the umbilicus. b, The incision is carried down to the fat overlying the peritoneum and the anterior bladder wall. c, The medial portion of the rectus muscle on each side is exposed and freed anteriorly and posteriorly down to the symphysis to permit wide retraction. d, The bladder wall is grasped with Allis clamps after dividing the fatty layer which covers it. The anterior peritoneal reflection is dissected upwards.

culature. Two had very complicated problems that were seen before the development of the suprapubic operation that we have described. Another patient had an irradiation fistula following the treatment of carcinoma of the cervix. Still another had tuberculosis in the bladder and but one functioning kidney. The clinical result has been gratifying in all of these cases. Their records are abstracted briefly.

Mrs D.B. aged 46 years, Carney Hospital No 361467 was admitted May 28, 1936. There was a history of vesicovaginal fistula following hysterectomy for fibroids. A second operation had been attempted to close the fistula and at this time a structured right ureter was tied. Suprapubic operation was performed by us June 9, 1936. The right half of the bladder was removed. Pathological report was tuberculosis. Incontinence persisted.

Left nephrostomy on December 9, 1937 was carried out to afford preliminary drainage and to reduce

Fig. 17g. Artist drawing. a, The bladder has been opened in the mid line and self-retaining retractor has been introduced. The urethral orifice is seen and ureteral catheters have been passed. The fistula is exposed but the artist has placed it higher than the usual position. b, Four traction sutures of fine black silk are introduced. The dissection is begun by incising the margin of the fistulous opening. c, The bladder is carefully separated from the sigmoid with a fine scalpel. The dissection is completed. There is free mobilization of the bladder and vagina. f, The vaginal opening is closed with interrupted sutures. g, No. 1 or 00 chromic catgut. h, The vaginal portion of the fistula is closed.

the risk of ureteral transplantation in the case of a single kidney. Left ureterointestinal anastomosis was performed on January 15, 1938. The result was satisfactory. The patient had a spinal fusion operation for tuberculosis in December 1934 with no untoward complications. She was last seen on December 16, 1947, almost 10 years after ureterointestinal anastomosis at age 58 years. She reported a good appetite. Her weight had remained the same for several years. She was drinking about 3 quarts of liquids every day and said that there had been no diminution in her rectal output. The intervals between voidings were sometimes 2 to 3 hours by day, nocturia once. She looked very well. Her color was

Fig. 3. Artist's drawing a. A second layer of interrupted sutures of No. 00 chromic catgut is applied in the vaginal wall when possible. Because of tension this layer has to be omitted in some cases. b. The closure of the bladder is begun with interrupted sutures of No. 00 chromic catgut in the bladder musculature, avoiding the mucosa. c. The closure of the muscular layer is completed. d. The bladder mucosa is closed with a running suture of No. 00 or 000 chromic catgut. e. The vesicovaginal fistula is now closed. The urethral and ureteral orifices are uninjured.

good. Blood pressure 155/75. The abdomen was not remarkable except for weakness of its wall in the regions of the scars. Fasting nonprotein nitrogen was 62 milligrams. The nonprotein nitrogen was 57 milligrams in April 1944. Intravenous pyelograms showed faint excretion of dye by the left kidney in 25 minutes with evidence also of some dye in the sigmoid. This appears to have been a satisfactory clinical result in a difficult problem in spite of present sign of impaired renal function.

Mrs. G. H. aged 40 years. Carney Hospital No. 381817 was admitted June 15, 1938. History of panhysterectomy for pelvic inflammatory disease followed by a vesicovaginal fistula and two unsuccessful repair operations. At examination a large fistula was found close to the ureters and heavily incrustated with urinary salts. A suprapubic cystostomy was performed first to prepare the bladder and vagina for subsequent plastic surgery. Uretero-intestinal anastomosis was refused. Colpocleisis was

Fig. 4. Anterior drainage. a, The anterior bladder is closed with interrupted extra-mucosal sutures of No. 1 plain catgut. b, A mushroom catheter about 26 French drains the bladder to the apex of the incision. c and d, The wound is closed. Small rubber tissue clips drain each side of the bladder and the perivesical space at the lower angle of the wound. done by Dr Phaneuf on August 3, 1938 and secondary closure of small pool of urinary leakage on October 14, 1938. Patient was discharged November 13, 1938 voiding normally incontinence relieved.

She returned to the hospital in 1939 because of domestic difficulties arising from the interruption of normal marital relations. Left retrointestinal neostoma was performed on November 7, 1940 ureterointestinal anastomosis on February 5, 1940.

vaginal plastic operation to reopen the vagina, by Dr Phaneuf March 2, 1940. Patient was last seen in the office on November 4, 1942. She had been perfectly well. Complete examination was not possible because she was leaving for California the next day. She looked well, had good color and a clean moist tongue. The abdomen was essentially normal. Intravenous pyelograms in July 1944, showed excretion of the dye by both kidneys in 5 minutes.

There was moderate dilatation on the right side. The clinical result seemed satisfactory.

Mrs. B. C. aged 37 years, Carney Hospital No. 394470 was admitted December 2, 1939. There was a history of panhysterectomy in August 1939 followed by vaginal fistula. After an attempt to close this in October 1939 the patient had developed an enterovaginal fistula. Carney Hospital diagnosis after urological study was fistulas—vesicovaginal, enterovaginal and ureterovaginal. Closure of enterovaginal fistula was carried out by Dr. Phaneuf on December 13, 1939. The fistulous tract was found to lie between the vaginal cuff and an adherent loop of ileum.

Right ureterointestinal anastomosis was done on March 28, 1940. Left ureterointestinal anastomosis on July 30, 1940. Patient was last seen in September 1947, over 7 years after the ureteral transplantations. Her general condition was excellent. Fasting non-protein nitrogen was 40 milligrams. Intravenous pyelograms showed excellent excretion of the dye by both kidneys in 5 minutes. There was slight dilatation on the left side. The clinical result seemed very satisfactory.

Mrs. E. B. aged 35 years, Carney Hospital No. 381424 was first seen in January 1938 when a urethrovaginal fistula followed operation for the removal of a large infected cyst or diverticulum of the urethra. Immediate repair was attempted without success. Suprapubic cystostomy and plastic operation upon the outlet of the bladder was done in November 1938. Incontinence persisted. Patient continued to wear suprapubic tube. Plastic reconstruction of urethra was carried out in June 1941 without success. Hysterectomy was performed by Dr. Phaneuf for fibroids and endometriosis and chronic salpingo-oophoritis in July 1942.

Left ureterointestinal anastomosis was performed on September 16, 1943. Right ureterointestinal anastomosis on July 17, 1944. Patient was last seen in July 1947. Nonprotein nitrogen was 40 milligrams on July 10 and 28 milligrams on July 15. Blood pressure was 130/90. Intravenous pyelograms showed the dye to be excreted by both kidneys in 5 minutes. There was slight dilatation of the renal pelvis and ureter on each side (Fig. 5). The clinical result seemed satisfactory.

Mrs. A. S. aged 52 years, Carney Hospital No. 446056 was admitted November 30, 1944. There was a history of cauterization of a urethral caruncle in 1939. This was repeated in 4 months and incontinence followed. There had been 4 unsuccessful attempts to repair the urethra between 1940 and 1943. Examination at the Carney Hospital revealed the urinary meatus lined with slough. The anterior vaginal wall was intact but scarred. Urethral destruction considered too complete for further plastic surgery.

Right ureterointestinal anastomosis was performed on September 22, 1944. Left ureterointestinal anastomosis on May 1, 1945. Patient was last seen in October 1947. Nonprotein nitrogen was 42 milli-

Fig. 5. Intravenous pyelogram in case of Mrs. F. B. Carney Hospital No. 381424, three years after ureterointestinal anastomosis.

grams on October 6 and 32 milligrams on October 10. Intravenous pyelograms showed the dye to be excreted by each kidney in 5 minutes. There was slight dilatation on the right side. The clinical result seemed very satisfactory (Figs. 6, 7, 8 and 9).

Mrs. B. E. aged 65 years, Carney Hospital No. 464687 was admitted September 9, 1946. There was a history of large vesicovaginal fistula beginning in September 1944 following a program of x-ray therapy and radium completed in August 1943 for the treatment of epidermoid carcinoma of the cervix grade 3. There had been one unsuccessful attempt to close the fistula by a vaginal operation combined with suprapubic drainage. Examination by the authors disclosed no evidence of persistent malignant disease. The vagina was 2 to 3 centimeters in length. The urethra was absent except for its distal third. Cystoscopy found the region of the trigone to be replaced by an area of slough and necrosis.

Exploratory laparotomy to exclude persistent cancer and right ureterointestinal anastomosis was performed on September 23, 1946. Left ureterointestinal anastomosis on October 17, 1946. The immediate result was very satisfactory. A letter received from the family physician in July 1947 stated: Her general condition is excellent. Except for the times when she is nervous and upset, her control is excellent. The blood pressure was 140/86. The non-protein nitrogen was 29. The intravenous pyelograms showed no evidence of either hydronephrosis or hydroureter.

The whole problem of ureterointestinal anastomosis and the technique employed at the

SUMMARY OF METHODS USED IN CLOSING

Vaginal flap method. Reconstruction of urethra (Cases 3, 33)	2
Total	40

*The vaginal flap method consisted of making a vaginal incision through or around the fistula, developing the vaginal flaps, mobilizing the bladder, closing the bladder opening with base catgut and the vaginal incision distal or were alloy wire or tent.

†Case 4. Vaginal closure by another surgeon after failure at the Carney Hospital.

Carney Hospital will be discussed in a later communication from the Urological Department.

RESULTS

There was no fatality in this series of 40 cases. The end result in 39 cases showed the patient to be cured. The case of 1 patient is not completed. A short summary follows.

CASE 36. Mrs. B. T. had a large vesicovaginal fistula about 3 centimeters in diameter. This had occurred on March 9, 1938, as a result of the high forceps delivery of her third child, a large male child who had died at birth. This delivery had been complicated by puerperal sepsis. The fistula which was situated high under the symphysis pubis could not be exposed for closure through the vagina. She also had a myomatous uterus the size of a 3 month gestation. The patient was operated upon at the Carney Hospital on June 18, 1946, a panhysterectomy and double salpingo-oophorectomy being performed. She made a satisfactory recovery. On October 18, 1946, she had an intravesical closure of the fistula by the method which we have presented under continuous spinal anesthesia. This was the most difficult operation for vesicovaginal fistula that we had thus far performed. She was discharged from the hospital on December 8, 1946, at which time she voided large amounts of urine at one time on the previous day having passed 12 ounces about 360 cubic centimeters of urine.

Examination by Dr. Phaneuf, office on January 2, 1947, showed the following: The abdominal incision was well healed. On the introduction of a Sims

speculum a small amount of urine was found in the vagina. The vaginal scar which was hidden under the hymen could not be seen. It was found to be perfectly smooth on palpation. On close observation after some time the escape of a minute quantity of urine was observed as it came from the right side of the scar. Thus the fistula, which originally had been the size of a silver half dollar, had been converted into a pinpoint opening.

The patient had returned to her home in California. A letter received from Dr. Frank Himmann of San Francisco in June, 1947, stated that cystoscopy had revealed a small fistulous opening in the bladder about 4 millimeters in diameter, in the superior portion of the scar on the right side. A functioning right ureter was not found. He felt hopeful that this remaining fistula could be closed successfully.

ABSTRACT OF CASES

The 5 case abstracts that follow are reported because of their unusual interest.

CASE 13. Mrs. A. S., an obese woman 59 years of age, had had a supravaginal hysterectomy for fibroid in a neighboring state. Sometime thereafter she had bleeding from the cervical stump and operation consisting of excision of the cervix through the vagina, was performed. The trigone of the bladder was removed with the cervix. When she was examined at the Carney Hospital she had a large vesicovaginal fistula which occupied the vaginal vault. The ureteral orifice on each side was caught in the scar and could be seen ejecting urine. On March 25, 1938, a colpocleisis was performed, alloy wire sutures being used. The convalescence was uneventful. On April 13, 1938, the alloy wire sutures were removed. Urinary continence had been established. On May 23, 1938, an examination showed the vagina to be 5 centimeters in depth. The patient had urinary control and was enjoying good health.

CASE 14. Mrs. G. H., 40 years of age and reported previously as a case of ureterointestinal anastomosis, had been operated on elsewhere on July 20, 1917, the operation consisting of a panhysterectomy and double salpingo-oophorectomy for pelvic inflammatory disease. The bladder had been injured at the time of operation and a vesicovaginal fistula had appeared immediately. On September 1, 1937, she was operated on again by the same surgeon, an abdominal closure of the vesicovaginal fistula being attempted. This was unsuccessful. On December 15, 1937, a vaginal closure of the fistula was undertaken again without success. She was referred to one of us on April 28, 1938, when an examination was made. A lighted speculum placed in the vagina revealed a large fistula at the apex of the vaginal vault. The opening was filled with a mass of urinary concretions. The vulva, the vagina and the inner aspects of the thighs were markedly excoriated. Later urological studies revealed that the left ureteral orifice was close to the margin of the fistula. Much scar tissue had

Fig 9.

formed subsequent to the two previous attempts at closure. The fistula was pulled upward under the symphysis and was inaccessible for closure through the vagina. The patient was given the choice of two methods: transplantation of the ureters into the sigmoid or colpocleisis. It was explained to her that colpocleisis meant the cessation of marital relations. She was emphatic in stating that future marital relations meant nothing to her and she chose the second of the two procedures.

On August 23, 1938, a colpocleisis was performed at the Carney Hospital. This healed except for a small area in the line of suture which allowed the leakage of a small amount of urine externally. On October 24, 1938, this defect was closed successfully. She was now continent and voided through the urethra. Later however she became dissatisfied with the cessation of her normal marital life and she demanded that the vagina be reopened. On December 3, 1939, one ureter was implanted in the sigmoid while the second was similarly treated on February 5, 1940. On March 12, 1940, a vaginal plastic operation was performed to reopen the vagina. A large glass dilating plug was introduced in the

vagina and was worn constantly. She was next seen in the office by one of us on April 11, 1940. The vaginal introitus and vagina admitted two fingers. The vesical fistula was readily felt and admitted the tips of the two examining fingers. The vagina was healthy in appearance; there was no irritation present and the operative results appeared to be satisfactory. Coitus had been indulged in. She was advised to discard the glass vaginal plug during the day but to wear it at night. On May 28, 1940, the vagina appeared to be roomy and she was advised to continue to wear the large glass plug at night and to continue with sexual congress. She failed to keep subsequent appointments but returned to the office on Febru-

Fig. 1. Intra-cervical pyelogram in Case 5. Mrs. M. H. Healed exocervical fistula, polypoid disease of the kidneys, and ureterovesical transplant in on the right side.

ary 20 1941. She had not worn the glass plug since August 1940. The vagina was somewhat contracted at the junction of the middle and lower thirds. The intritus admitted to examining fingers. The narrowing was believed to be due to disease. A medium-size glass plug was inserted and he was asked to retain it in six months for the introduction of a larger one. She was entirely satisfied with her urinary control. She was last seen in May 12 1941 when the plug was not used. The vaginal introitus readily admitted two fingers. The vaginal wall was soft and healthy in appearance. Medium bulbous genital speculum could be used without difficulty. The second to the largest glass vaginal plug can be introduced with some difficulty. Urinary control is satisfactory.

CASE 25. Mrs. C. O. C. 42 years of age was operated on at the Cleveland Hospital for exocervical fistula in October 1 1942. The fistula had developed after an instrumental delivery of her first child. Urinary pre-symptoms. Three operations had been performed. Another attempt in a attempt to close the fistula. The first operation was performed in 1935. This was not successful. The second operation was performed on August 11 1941 and consisted of vaginal hysterectomy and closure of the fistula which resulted in failure. The third operation was performed in October 12 1941 and consisted of vaginal closure of the fistula. This also resulted in failure. At the time of her admission to the Cleveland Hospital the vagina contained considerable amount of discharge due to the vagina. The patient had in the past of the thigh was recovered. The degree of urinary salts. Careful preliminary measures are necessary to prepare these areas for

surgery. The operation which was performed on October 3 1941 consisted of a left Schuchardt incision and the vaginal closure of the fistula after free mobilization with interrupted sutures. No. 6 chrome catgut placed in the bladder wall in a transverse direction. This completed closed the bladder opening. Next a flap of mucosa of the vagina was split from the left vaginal wall. A flap was sutured over the region of bladder repair by means of interrupted sutures of No. 6 chrome catgut. The reinforced bladder suture line. Finally the vaginal mucosa was closed with five interrupted sutures of steel thread. The Schuchardt incision repaired and a suprapubic cystostomy was performed. The convalescence was uneventful. The suprapubic catheter was removed on October 21 1942 and the suprapubic sinus had healed completely in October 5 1942. The alloy wire sutures were removed on October 25 1942. There was no sign of a fistula and the patient was allowed out of bed on that day. She was examined in the office on December 6 1942. July 5 1943 and May 31 1944. All examinations showing well healed fistula and urinary continence.

CASE 26. Mrs. M. H. 39 years of age had had a paralytic rectum and double salpingo-oophorectomy for uterine myoma in April 4 1941. Shortly after operation a large exocervical fistula was found and the patient appeared to be completely cured. A urologist was called for consultation. In addition to the large exocervical fistula, he discovered ectopy of both ureters at the bladder level. He performed bilateral nephrostomy in April 6 1941 and at this time learned that the patient had congenital polycystic disease of the kidneys. When urine later began to flow from the vagina through the fistula opening the nephrostomy incisions are allowed to close. Subsequently the surgeon who had done the hysterectomy performed a vaginoplasty for closure of the fistula. Neither of these being successful, he was referred to the Cleveland Hospital for complete urological studies. It was found that the left ureter was patent and that the right ureter was obstructed at about 4 centimeters above its entrance to the bladder. A right ureteral fistula had occurred along the structure and this fistula was in contact with the ovaries on vaginal opening permitting the escape of urine from the right kidney. The first step in the course of treatment was the implantation of the right ureter in the postero-superior portion of the bladder. Healing was satisfactory and the function of the right ureter was demonstrated by roentgen. The next step was an attempt to close the exocervical fistula through the vagina on December 14 1944. The opening of the left ureter was closed with catheter of the fistula. For this reason a ureteral catheter was passed on that date to lessen the likelihood of ureteral injury during the operation. A left Schuchardt incision was made. The fistula was hard to expose. There was extensive scar tissue resulting from the first two attempts at closure and the right

end of the fistulous opening was pulled upward and behind the right pubic ramus. It was impossible to separate the vagina from the bladder under these conditions. Therefore the edges of the fistula were pared according to the Sims technique and the opening was closed with six interrupted sutures of No. 30 steel alloy wire. The Schuchardt incision was closed and suprapubic drainage was established. The catheter in the left ureter was left *in situ* for a few days. On January 16, 1945, the six steel alloy wire sutures were removed. There was still a slight escape of urine into the vagina on the right side. The patient was examined at the office on March 7, 1945, there was persistent urinary leakage from the vesicovaginal fistula.

On May 21, 1945, intravesical closure of the fistula was carried out by the authors under continuous spinal anesthesia by the technique described. The patient never passed any urine through the vagina from that time on. Healing took place by first intention. She was allowed to void on the twenty-first day. She was discharged from the hospital on June 21, 1945, the fistula being closed and both kidneys draining into the bladder. Intravenous pyelograms in July 1945 showed fair renal function on each side with good concentration of the dye in the 25 minute film (Fig. 10). Changes in the kidney pelvis due to polycystic disease are seen. The right ureter which has been transplanted to the dome of the bladder is shown with no significant dilatation. On August 18, 1945, examination at the office revealed the vaginal vault to be smooth, the anterior vaginal wall to be well healed, the fistula to be closed, and the result satisfactory. At the last office visit, April 17, 1947, the patient looked very well and had no symptoms. A voided sample of urine showed no abnormalities microscopically. At abdominal examination both kidneys were found to be palpable and the right one smaller than the left. Blood pressure was 175/85.

SUMMARY AND CONCLUSIONS

1. The distressing condition of vesicovaginal fistula originally was due to obstetric causes. The majority of urinary fistulas seen today follow operations on the female pelvic organs. The latter are the more difficult to repair because of their inaccessibility and the firm scar tissue which surrounds them.

2. The first operation on record for the closure of vesicovaginal fistula is that of Mr. Montague Gosset of London in January

1834. He had used gilded silver wire sutures. George Hayward of Boston reported a successful operation in 1839 as well as two others in 1851.

3. J. Marion Sims closed his first vesicovaginal fistula in May 1849, having operated on the slave girl Anarcha for the thirtieth time and having used silver wire sutures for the first time. It is very probable that Sims knew nothing of the work done in London when he proposed the silver wire suture.

4. The various procedures used in closing vesicovaginal fistulas are tabulated.

5. We are of the opinion that most vesicovaginal fistulas can be closed by the vaginal route.

6. For the few cases in which the fistula cannot be exposed through the vagina, we describe and illustrate an intravesical operation which has given us excellent results.

7. In 6 cases in this series for reasons that have been presented, ureterointestinal anastomoses were performed with satisfactory results.

8. The advantage of suprapubic drainage in the management of difficult vesicovaginal fistulas is emphasized.

9. The preoperative and postoperative care as well as the suture material are discussed.

10. Thirty-four cases (plus Dr. Graves' 6 cases of ureterointestinal anastomosis) with their end results are reported.

Fig. 1 Toetip plethysmograms tracing from a normal subject on the left, and from a hypertensive subject on the right. Note the differences in both the position of the dicrotic notch and in the amplitude of the alpha waves in both

records (In these and in all subsequent tracings the calibration on the left represents a volume change amounting to 20 cubic millimeters. Spacing between the ordinates equals 5 seconds.)

intervals following both unilateral and bilateral sympathectomy

The plethysmograms were calibrated frequently in order to insure accurate standards for measurement and comparison. The analysis of all the tracings was based on the contour of the volume pulse wave, the amplitude of the volume pulse, the amplitude of the alpha waves, the overall volume and the changes which followed attempted vasodilatation.

In most patients physical examination was supplemented by teleroentgenograms, electrocardiograms and intravenous pyelograms. Retinal changes were evaluated by ophthalmologists. Renal function was determined both by the excretion of diodrast as noted on the pyelogram and by the excretion of phenol sulfonphthalein. The blood pressure was measured sphygmomanometrically at frequent intervals. The changes in blood pressure which followed sodium amytal were measured in all but 7 of the 30 patients who underwent operation.

RESULTS

Figure 1 illustrates the plethysmogram of both a normal and an untreated hypertensive patient. Although the volume pulses of both are characterized by a sharp peaked apex, by a distinct dicrotic notch and by a more vertical systolic than diastolic limb, it is to be noted that the dicrotic notch is inscribed nearer to the apex and as a rule the magnitude of the alpha deflections is greater in the hypertensive than in the normotensive subject. The proximity of the dicrotic notch to the apex of the

volume pulse appears to be related to the height of the diastolic pressure since the dicrotic notch is in general found to be at a higher position on the diastolic limb in the presence of severe rather than of mild diastolic hypertension. However, since we have encountered considerable overlapping, too much prognostic significance has not been ascribed to volume pulse wave contour changes of this variety. On the other hand, certain other alterations in the intrinsic digital volume fluctuations may be prognostically important since on occasion they may reflect the development of diseases which not infrequently complicate hypertension. Thus a decrease in the normal slope inequality of the systolic and diastolic limbs, a blurring or disappearance of the dicrotic notch, and a reduction in the amplitude or a complete disappearance of the alpha waves may represent coexist

Fig. 2 Toetip plethysmogram in a patient with both hypertension and arteriosclerosis. Note the absence of the dicrotic notch, the inconspicuous alpha waves, and the loss in the normal slope inequality of the systolic and diastolic limbs.

Fig. 5 Toetip plethysmograms from a hypertensive patient before and after nitroglycerine. Control tracing on the

left. Note that following nitroglycerine the primary change is manifested by a fall in the position of the diastolic notch.

ences of previous investigators which demonstrated that the administration of nitrates may be followed by vasodilatation resulting from a direct effect upon the smooth muscle of the smaller blood vessels suggested the use of nitroglycerine as a means of reducing vasomotor tone. Accordingly this drug was administered sublingually in doses ranging from 1/100 to 1/150 grain to 98 hypertensive patients. The plethysmographic changes which ensued could be classified into a number of broad categories: in one there was an increase in volume pulse amplitude and a fall in the position of the diastolic notch (Fig. 3) in another the amplitude increased but the pulse contour remained unchanged (Fig. 4) in a third a characteristic lowering in the location of the diastolic notch was observed (Fig. 5) but there was either no change or an actual decrease in the amplitude of the volume pulse in a fourth the volume pulse amplitude decreased and the diastolic notch fell (Fig. 6) and in the fifth no plethysmographic alterations were evident. These

distinctions are not absolute. For example the extent to which both the diastolic notch descends and the volume pulse amplitude increases may be slight or moderate or marked. Ordinarily an increase in the amplitude of the volume pulse deflections was accompanied by an increase in the frequency and in the amplitude of the alpha waves. Exceptions to this relationship were encountered and subsequent results indicated that from the prognostic viewpoint alterations in alpha waves were not as significant as were corresponding changes in the volume pulse waves.

Usually the plethysmographic patterns of corresponding digits in each individual were similar. On occasion they differed markedly in that the amplitude of the various intrinsic volume deflections both before and after vasodilatation were much greater on one side than on the other (Fig. 7). It is evident that differential plethysmographic patterns of this type indicate the existence of structural vascular disease. Such findings also demonstrate that

Fig. 6 Toetip plethysmograms from a hypertensive patient before and after nitroglycerine. Control tracing on the

left. Note that after nitroglycerine the volume pulse amplitude decreased while the diastolic notch fell to the baseline.

Fig. 7. Toesup plethysmograms from a hypertensive patient. Upper tracings from the left and right great toes be-

fore lower tracings from the same toes after nitroglycerine. Note the marked differences in both sets of tracings.

the rate at which the pathological alterations in the different vascular beds develop may vary considerably.

The change in the volume fluctuations of the digits which follow the administration of nitroglycerine has been employed as an index for estimating the functional occlusive as opposed to the structural occlusive component in each instance of hypertension. Since the functional integrity of a vascular bed may be measured by its ability to dilate, the absence of any plethysmographic change after the administration of nitrites presumably indicates that fixed organic vascular disease is present. A decrease in the volume pulse amplitude even when coupled with a decline in the position of the diastolic notch is evidence that structural alterations in the blood vessels have developed. The reduced amplitude may be explained by assuming that a portion of the circulating blood volume has been diverted temporarily to relatively uninvolved areas in which the peripheral resistance has been reduced by pharmacologic vasodilatation. Conversely, an increase in the volume pulse amplitude especially when accompanied by characteristic changes in the contour of the volume pulse and by increases in the amplitude of the alpha waves strongly suggests

the presence of vasospasm. The magnitude of these alterations will represent the relative importance of increased vasomotor tone in each instance of hypertension.

At this point it may be stated that prognostic usefulness of the plethysmographic method has been established by the operative results. The procedure was originally designed as a method of study of the finer circulatory dynamics in hypertension and not as a means of selecting patients for sympathectomy. It is only as a result of analyzing the plethysmographic data and contrasting these with changes in arterial pressure after sympathectomy that there is justification for the statement that the criteria which have been described may be regarded as an index of postoperative results. Hence the present report details only the studies of those hypertensive patients who underwent operation.¹ It is evident from this study that the presence of factors such as cardiac enlargement, electrocardiographic changes, severe grades of hypertensive retinopathy, urinary abnormalities and diminished renal function cannot by themselves be considered as absolute indicators of poor surgical results. Fur-

Fig 9 Toetip plethysmograms following lumbodorsal sympathectomy. Tracing on the left obtained before and that on the right obtained after nitroglycerine administration. Note the decrease in the volume pulse amplitude which followed the administration of nitroglycerine.

thermore the data suggest that an excellent therapeutic response may be expected in appropriately selected hypertensive patients who are more than 50 years old.

The sodium amyltal test was performed in 23 of the 30 patients subjected to operation. The findings¹ have been compared with the plethysmographic changes after nitroglycerine and with the arterial pressure after sympathectomy. The contrast between the amyltal test and the plethysmographic method is apparent. By the amyltal test an accurate forecast was made in but 8 of the 23 patients while by the plethysmographic method a correct result was prognosticated in 27 of the 30 patients. Plethysmography led to erroneous conclusions in 3 patients.

See Table II in reprint.

THE PLETHYSMOGRAM FOLLOWING SYMPATHECTOMY

After sympathectomy vascular tone is dependent upon local metabolic and environmental requirements and upon the concentration of circulating humoral vasoconstrictor and vasodilator substances (3). Variations in volume pulsations may therefore be quite pronounced unless observations are made under relatively constant conditions. Aside from this interruption of the sympathetic outflow to an extremity whose vascular bed has been in a state of increased tonus is followed by a maximal increase in the height of the volume pulse by a loss of vasoconstrictor reflexes and by a disappearance of the alpha waves (Fig 8). After attempted vasodilatation by nitroglycerine the volume pulse amplitude either remains

unchanged or it actually decreases (Fig 9). Conversely, the failure to elicit these changes after sympathectomy is presumptive evidence that complete vascular denervation has not been attained. This observation is of importance since it may account for the poor operative results in patients deemed suitable for sympathectomy by the previously described plethysmographic criteria. As examples may be cited two of the patients in the series who although plethysmographically considered as excellent candidates developed no reduction in the level of the systemic arterial blood pressure after sympathectomy. The plethysmograms postoperatively were essentially similar to those obtained preoperatively in that large amplitude alpha waves persisted, nitroglycerine continued to induce a distinct increase in the volume pulse amplitude, and reflex vasoconstrictor activity could still be demonstrated. From a consideration of these facts it appears that the plethysmographic method may offer means of evaluating the extent and adequacy of operations on the sympathetic nervous system. Therapeutic implications are apparent.

Digital plethysmography has been of additional value in that by this method we have been able to demonstrate objectively the basis for the acroparaesthesias in the fingers which not infrequently follow sympathectomy. Fingertip tracings in these cases have revealed an increase in vasomotor tone as evidenced by the fact that the volume pulse amplitude postoperatively is reduced when compared with the amplitude preoperatively.

DISCUSSION

It is now generally believed that there are no structural vascular alterations until the later stages of essential hypertension are reached and that elevations in the level of the diastolic pressure are induced by increased vasoconstrictor activity mediated through humoral or neuropressor mechanisms. That the increase in total effective peripheral resistance may be primarily related to augmented vasomotor tone in selected areas of the systemic arterial bed is also generally accepted. Since bilateral sympathectomy aims at reducing the vasomotor tone of the splanchnic area and of the lower extremities, in theory at least its effectiveness

will be limited by the following factors, namely, that segments of the arterial bed other than the splanchnic area and the lower extremities are responsible for the increased peripheral resistance that the increased resistance is induced by humoral rather than by neurogenic mechanisms and that structural alterations have developed. A consideration of these facts enables one to understand why inferences based only upon a simple measure of the arterial pressure after the administration of the various pharmacologic agents which have been advocated so frequently lead to erroneous conclusions. For similar reasons the inherent fallacy of basing prognostications upon the presence or absence of retinal urinary electrocardiographic and roentgenological changes is apparent. While as a generalization it is true that the existence of such alterations is indicative of an advanced stage of hypertension, the results of our study demonstrate that each patient must be evaluated individually and that the occurrence of these organ changes is not incompatible with excellent operative results. By the same token the fact that a hypertensive patient is past the age of 50 years means that in all probability he has had an elevated blood pressure for a longer period than a younger patient and that the likelihood of generalized vascular changes has correspondingly increased. As with the other factors mentioned this concept is only valid in broad terms and the importance lies in exactly individualizing each patient. We are therefore forced to the conclusion that the indications for operation should be essentially clinical and that the reliance on the prognosis of operation can be placed on microplethysmographic examination.

At the present time there is no practical method that is available to evaluate the factor of splanchnic vasoconstriction but in contradistinction to the other procedures which have been previously advocated microplethysmography can offer accurate objective information concerning the vascular state of at least a portion of the arterial bed which is to be denervated by sympathectomy. As Goetz has emphasized digital plethysmography evaluates the "ultimate" circulation and although there can be no argument with the technique a logical and valid criticism of the procedure

may be based on the use of nitroglycerine, especially since the nitrites and sympathectomy induce vasodilatation by entirely different mechanisms. We are cognizant of this possible source of error, and are analyzing this problem by contrasting the plethysmographic changes following the use both of nitroglycerine and tetraethylammonium. The results of these experiments are to be presented in a future report.

SUMMARY AND CONCLUSIONS

1 A microplethysmographic method is described for selecting hypertensive patients who are to benefit from sympathectomy. This is based on the use of a new direct ink recording photoelectric microplethysmograph.

2 The procedure entails an analysis of the volume changes occurring in the phalanges before and after the attempted release of vasomotor tone by nitroglycerine.

3 It was demonstrated that one of five volume alterations follow the sublingual administration of nitroglycerine and that satisfactory operative results occur only in those patients who develop a pronounced increase in the volume pulse amplitude after nitrite ingestion. The simultaneous occurrence of an increase in the amplitude and in the frequency of the alpha waves is a good prognostic sign but the

absence of such changes does not preclude a significant postoperative reduction in the arterial pressure.

4 The plethysmographic method predicted the operative results correctly (whether favorable 20 patients or unfavorable 7 patients) in 27 of the 30 subjects. In contrast the sodium amytal test led to accurate conclusions in 8 of 23 patients.

5 The inherent fallacy of the amytal test and of the other criteria currently employed as indices of operability is discussed.

6 Aside from its usefulness as a means of selecting patients for operation, microplethysmography has the added value of being able to estimate the postoperative extent and completeness of sympathectomy.

7 A possible error in the procedure is mentioned. This depends upon the use of nitroglycerine as a vasodilator.

EFFECTS OF SUBLETHAL HEMORRHAGE IN NORMAL DOGS AND IN DOGS PREVIOUSLY TRANSFUSED WITH WHOLE BLOOD

RAY SEEVERS M.D., and PHILIP B. PRICE, M.D. F.A.C.S. Salt Lake City Utah

THE changes occurring in the circulating blood of man and animals following hemorrhage have been fairly well investigated. In an experimental investigation of hemorrhagic shock Price and his associates (12) have demonstrated what changes occur in the circulating blood of dogs following acute lethal hemorrhage. It is generally believed that following rapid severe hemorrhage there is a decrease in plasma protein concentration and in hemoglobin concentration proportional to the amount of fluid shifted into the blood stream. Elman (10) stated that after hemorrhage the most pronounced hemodilution occurred within the first hour and continued for 72 hours. Price reported (12) that following massive bleeding (34 c.c. per kgm.) there was an influx of fluid into the blood stream of 3.4 cubic centimeters per kilogram and an influx of red cells amounting to 3.8 cubic centimeters per kilogram within 5 to 6 hours. Although Price noted no increase in total circulating plasma protein mass following fatal hemorrhage in normal dogs, he found that after a single sublethal hemorrhage the total plasma protein mass returned to normal in 48 hours and plasma volume returned to normal in 24 hours. Elman (8) stated that following sublethal hemorrhage correction of the lost albumin fraction began in the first 6 hours and was still incomplete at 7 days. He noted also (9) that in fasting dogs which were bled rapidly and in which the blood was replaced with saline there was a drop of 20 to 22 per cent in protein concentration. This value did not change for 6 hours indicating that there was no rapid mechanism for the restoration of serum protein concentration. Cutting found that after the removal of

40 per cent of the blood of a rat the total protein mass returned to the original level in 12 hours. Calvin (4) stated that following subacute hemorrhage in a dog there was evidence of movement of fluid into the circulation within a few hours and that protein (primarily albumin) entered with this fluid. Beattie (5) concluded that within 2 hours of hemorrhage, in cats anesthetized with nembutal there was evidence of movement of plasma proteins into the blood stream.

Relatively little attention has been paid, however to the changes which occur in the circulating blood of animals following hemorrhage when those animals have been previously transfused with whole blood. Since preoperative transfusion of patients in anticipation of a sanguineous operative procedure is common practice it was thought that transfusion of experimental animals prior to rapid, sublethal hemorrhage, and comparison of the posthemorrhagic response to that of control dogs subjected to similar hemorrhage might shed some light on the efficacy of the practice. This paper is a report of an experimental study of that sort.

METHODS AND CALCULATIONS

The first group of dogs were normal healthy animals with an average weight of 17.6 ± 1.3 kilograms. This group of animals was used as controls.

They were anesthetized lightly with intravenous 5 per cent sodium pentobarbital solution and were prepared for the experiment by cannulating the carotid artery intubating the trachea, and exposing the femoral vein. Following a basal period of 1 to 2 hours, during which time preliminary determinations were made, the dogs were bled rapidly from the carotid artery. The effects of this bleeding were then studied for 5 hours.

From the Department of Surgery, University of Utah Medical School, Salt Lake City, Utah.

Added by grant for the study of Surgical Shock from the U.S. Public Health Service.

The second group the experimental animals consisted of normal healthy dogs averaging 17.0 ± 1.1 kilograms. They were prepared in the same manner as the first group except that following the "basal" period they were transfused with well matched, citrated, whole blood which had been freshly drawn from healthy dogs. After transfusion studies were made for a period of 3 to 5 hours. The dogs were then bled rapidly from the carotid artery and the various determinations made hourly for 4 to 12 hours.

All determinations were made by means of standard methods and procedures which have been described more completely elsewhere (12, 14). In brief however the dye method (T 1824) with Price and Longmire's (13) modification of the Gibson and Evelyn technique was used for plasma volume determinations and the falling drop method of Barbour and Hamilton checked occasionally by Kjeldahl measurements was used for protein concentration determinations.

Statistical analysis consisted of computing the standard error of all means and of testing the significance of those means. When it was desired to show a significant difference between means the standard error of the difference between means was tested for significance.

RESULTS

This study included 2 series of experiments. The first, a control study consisted of 6 normal dogs which were bled rapidly from the carotid artery and in which the posthemorrhagic response was studied for 5 hours. The bleeding required 3 to 5 minutes and averaged 150 ± 7 cubic centimeters per kilogram.

Fig. 1. Control study. Effects of rapid sublethal hemorrhage in normal dogs anesthetized with sodium pentobarbital. Mean values of 6 experiments.

The second series consisted of 10 dogs which were transfused before being bled. Five of these dogs were splenectomized in order to eliminate the factor of the expansile canine spleen and its consequent effects as an erythrocyte store. In general little difference was noted however between the splenectomized and nonsplenectomized dogs except in the response of the total hemoglobin mass after bleeding.

Each experiment in the second series consisted of 3 parts. First there was a 'basal' period prior to transfusion during which preliminary studies were made. These initial determinations made during the first $1\frac{1}{2}$ to 2 hours, represent normal values for the animal and hereafter will be designated basal values. The second part of the experiment began with the start of the transfusion which required

TABLE I.—AVERAGE VALUES DETERMINED BEFORE AND AT HOURLY INTERVALS AFTER RAPID SUBLETHAL HEMORRHAGE IN NORMAL DOGS ANESTHETIZED WITH SODIUM PENTOBARBITAL

	"Basal"	Immediately before hemorrhage observed values	Immediately after hemorrhage expected values	hour after hemorrhage	hours after hemorrhage	4 hours after hemorrhage	5 hours after hemorrhage
Hematocrit	$43.3 \pm .1$	43.4 ± 1.8		43.1 ± 1.9	42.5 ± 1.8	43 ± 1.7	44.0 ± 1.8
Circulating cell volume (c.c. per kgm.)	40.6	44.8	38.6	39.6	38.7	38.7	38.7
Plasma protein concentration (grams per cent)	$6.25 \pm .15$	$6.80 \pm .18$		$5.90 \pm .17$	$5.80 \pm .15$	$6.03 \pm .16$	$6.80 \pm .14$
Total plasma protein mass (grams per kgm.)	$83 \pm .17$	$189 \pm$	$33 \pm .1$	40 ± 18	41 ± 7	40 ± 10	$41 \pm .39$
Plasma volume (per kgm.)	45.5 ± 1.4	47 ± 1.6	38.4 ± 1.3	41.0 ± 1.8	$43.5 \pm .8$	$40.7 \pm$	40.9 ± 1
Blood volume (c.c. per kgm.)	85.1 ± 3.3	$92.0 \pm .8$	77.0 ± 7	80.6 ± 5	$80 \pm .5$	79.6 ± 4	79.6 ± 4

TABLE II.—AVERAGE VALUES OF THE CITRATED BLOOD USED FOR THE 10 TRANSFUSIONS

Amount of blood given per kgm. of recipient	$5.4 \pm .2$ c.
Amount of plasma given per kgm. of recipient	$1 \pm .3$ c.
Protein concentration	$4.86 \pm .59$ grams per cent
Hemoglobin concentration	$12.4 \pm .7$ grams per cent
Hematocrit	$43.7 \pm .8$
Amount of protein given per kgm. of recipient	$65 \pm .05$ gram
Amount of hemoglobin given per kgm. of recipient	$68 \pm .11$ grams

approximately 1 hour and terminated at the time of bleeding. The last value determined just before bleeding is referred to as the 'pre-hemorrhage' value and marked the beginning of the third or posthemorrhage portion of the experiment. After bleeding which required but 3 to 5 minutes and averaged 16.4 ± 1.2 cubic centimeters per kilogram, determinations were made at hourly intervals until 4 hours or more had elapsed.

The term 'expected' value has been used to refer to those values calculated from the previous value minus the amount of blood plasma protein lost by hemorrhage. For example, the 'expected' blood volume after hemorrhage was calculated by subtracting from the 'prehemorrhage' blood volume the amount of blood taken from the carotid artery during the bleeding.

Changes occurring after hemorrhage in normal dogs. The changes which occurred in the cir-

culating blood of the 6 animals comprising the control series are given in Table I and a graphic representation of some of those changes is shown in Figure 1.

Following hemorrhage the dogs on the average gave little if any evidence of hemodilution (Fig. 1). The small changes which occurred were not significant. Variations in hemoglobin concentration paralleled those in hematocrit.

There was no significant alteration in circulating cell volume from that expected following hemorrhage. No change in relative red cell size could be detected.

All dogs showed some reduction of plasma protein concentration after hemorrhage. The average 4 to 5 per cent reduction was however not statistically significant.

Following hemorrhage, return of small amounts of plasma protein to the circulation could be detected in most of the control animals. Five of the 6 dogs showed a slight increase in total protein mass above that "expected" after hemorrhage, but the average increase of 1.1 grams of protein (2.5 per cent of the entire protein mass) was not significant.

Blood volume showed an increase of 2.6 cubic centimeters per kilogram 4 hours after hemorrhage. This also was not a significant increase.

Changes occurring during and immediately following transfusion. Since the results of whole blood transfusions in normal dogs have been previously presented (14) the changes

TABLE III.—AVERAGE VALUES DETERMINED BEFORE TRANSFUSION BEFORE HEMORRHAGE (3 TO 5 HOURS AFTER TRANSFUSION), AND AT HOURLY INTERVALS AFTER HEMORRHAGE OF 10 DOGS TRANSFUSED WITH CITRATED WHOLE BLOOD THEN BLED FROM CAROTID ARTERY

	"Blood"	"Pre-hemorrhage"	"Expected"	hour after hemorrhage	hours after hemorrhage	hours after hemorrhage
Hemoglobin (grams per cent)	$5 \pm .4$	$18 \pm$		$7.3 \pm .5$	$7 \pm .4$	$17 \pm .3$
Hematocrit	$46.5 \pm .6$	$56 \pm$		$33 \pm .6$	$33.7 \pm .5$	$53 \pm$
Total hemoglobin mass (grams per kgm.)	$\pm .5$	$1 \pm$	$6 \pm$	$6 \pm$	$5 \pm .5$	\pm
Protein concentration (grams per cent)	$5.8 \pm .16$	$14 \pm$		$6.70 \pm .06$	$5.0 \pm$	$6.7 \pm$
Total protein mass (grams per kgm.)	$3.06 \pm .17$	$6.6 \pm .09$	$\pm .9$	$3.1 \pm$	$3.3 \pm .05$	$4.3 \pm .04$
Plasma volume (cc. per kgm.)	$\pm .6$	$40 \pm$	$40 \pm$	$34 \pm$	$34 \pm$	$36 \pm$
Blood volume (c.c. per kgm.)	8 ± 1	$5 \pm$	\pm	$67 \pm$	$66 \pm$	$70 \pm$
Blood pressure (mm. of Hg.)	$54 \pm .5$	$90 \pm .7$		$30 \pm$	$30 \pm .5$	$38 \pm .5$
Pulse	$166 \pm$	5 ± 6		66 ± 4	$70 \pm$	17 ± 7
Temperature	$38.6 \pm$	$41 \pm .7$		$38.8 \pm .7$	$38 \pm .7$	$39.3 \pm .6$

One hour following hemorrhage, total circulating protein mass (Fig. 2) increased above the expected value in 7 of the 10 dogs. In 2 experiments the influx of plasma protein into the blood stream was sufficient to return the plasma protein mass to its prehemorrhage value however the plasma protein increase observed in the other experiments was not great. Also the decrease in plasma protein below the expected value observed in 3 experiments was very slight. The average increase in plasma protein mass following hemorrhage was not significant.

An increase in plasma volume over and above the expected volume occurred in 9 of the 10 dogs 1 hour after hemorrhage. Average increase 1 hour after hemorrhage was 4.3 cubic centimeters per kilogram or 9 per cent above the expected plasma volume. Four hours after hemorrhage plasma volume was increased 5.9 cubic centimeters per kilogram or 13 per cent above the expected volume. These changes are illustrated in Figure 3. In 2 experiments plasma volume was increased above the prehemorrhage value, thus returning to the circulation an amount of fluid more than equal to the volume of plasma lost during hemorrhage. This average increase in plasma volume was statistically significant.

One hour and 4 hours after hemorrhage 6 of the 10 dogs showed an increase in blood volume above the expected volume. In 1 experiment blood volume returned to the prehemorrhage level at 4 hours. In those animals which showed a decrease in blood volume below the expected value there was no instance in which the decrease exceeded 5 per cent. In fact, most of these animals showed only a very slight decrease. The average increase of 6.5 cubic centimeters per kilogram at 4 hours (Fig. 2) was not significant.

During hemorrhage blood pressure fell precipitously from an average 150 millimeters of mercury to 50 to 60 millimeters of mercury. Recovery was rapid, however and usually blood pressure returned to within range (i.e. within 1 standard deviation) of the pretransfusion value in 15 minutes.

Following hemorrhage, there was usually a tendency for the pulse rate to increase but not enough to be considered significant.

There was a steady rise in temperature throughout the experiments. An average increase of 1.5 degrees from the start of the experiment to the time of hemorrhage was noted, and a further rise of 1.3 degrees from the time of hemorrhage to the end of the experiment was observed.

Respiratory rate, respiratory volume, and oxygen uptake were determined in 3 animals. No significant changes were noted in any of these values following hemorrhage.

DISCUSSION

The most striking change occurring in the circulating blood following hemorrhage was prompt hemodilution of greater or less degree due to influx of fluid into the circulation (Figs. 1 and 3). Although in the control animals some fluid entered the circulation after hemorrhage, it was not in significant amounts in the dogs that had been transfused just before hemorrhage however significant amounts of fluid did enter the circulation. A volume of fluid equivalent to 9 per cent of the original plasma volume was added to the circulation within the first hour on the average and by the end of 4 hours a volume of fluid equivalent to 13 per cent of the original plasma volume had entered the circulation. In the matter of fluid shifts therefore there appears to be a distinct difference between the normal dogs and those that had been transfused just before hemorrhage. However the size of these fluid translocations varied considerably and it is possible that these shifts depended more on the status of body hydration before the experiment than on the amount of blood added by transfusion. Although most of the fluid entered the circulation during the first hour in several experiments fluid continued to enter the circulation until 4 hours after hemorrhage.

In both series of experiments this influx of fluid following hemorrhage was sufficient to be reflected as changes in hematocrit, hemoglobin and plasma protein concentration. These values showed an immediate decrease during the first hour. The influx of red blood cells, which was about 4 per cent of the original total mass in both series, was sufficient to forestall further apparent hemodilution after the first hour.

THE NATURE OF POSTOPERATIVE HYPOPROTEINEMIA IN PATIENTS WITH GASTROINTESTINAL CANCER

IRVING M. ARIEL, M.D., Minneapolis, Minnesota

PATIENTS with gastrointestinal cancer frequently present variable degrees of emaciation and cachexia. Because of the high incidence and great mortality from gastrointestinal cancer a study was instituted to investigate some of the metabolic abnormalities that might exist. This report deals with the incidence and degree of hypoproteinemia in patients with gastrointestinal cancer and emphasizes the effect of surgery upon certain phases of nitrogen metabolism

PREOPERATIVE PLASMA PROTEIN CONCENTRATION IN PATIENTS WITH GASTRIC CANCER

One hundred patients with gastrointestinal cancer have been studied as to the state of their serum proteins. Serum protein for normal individuals has been found to range from 6.5 to 7.4 grams per cent. The average is 6.9 grams per one hundred cubic centimeters with a standard deviation of ± 0.47 gram per cent. In sharp contrast the average serum protein concentration in patients with gastrointestinal cancer is 6.1 grams per cent with a standard deviation of ± 0.6 gram per cent. Of the 100 patients examined 59 were found to have abnormally low levels (Charts 1 and 2) (8).

The cause of hypoproteinemia is not entirely clear. Several possibilities present themselves, namely: (1) deficient diets; (2) repeated hemorrhage; (3) a defect in the absorption of amino acid; (4) increased catabolism of the protein; or (5) some metabolic abnormality which prevents the synthesis of serum proteins.

Dietary deficiency. In an attempt to ascertain the role played by a deficient dietary intake in the production of hypoproteinemia the patients were divided into five groups

according to the degree of dietary deficiency. The mean serum protein level and the standard deviation were computed for each group.

The distribution of the serum protein determinations was plotted against variations in diet to show what effect if any dietary intake has on the serum protein level. Analysis of the data reveals no statistically significant difference between the means of the different groups which gave evidence of dietary deficiency. All protein values were significantly lower than normal (Chart 3).

It thus becomes apparent that variations in the degree and duration of dietary deficiency do not contribute by themselves significantly to the incidence and degree of hypoproteinemia in patients with gastric cancer.

Relationship of bleeding to hypoproteinemia. Bleeding is an important factor which might be responsible for an abnormal erythron or a low plasma protein concentration. In this series a patient was considered to present evidence of blood loss if he fulfilled any one of the following criteria: (a) history of blood loss (melena, hematemesis, etc.) within 6 months previous to his admission; (b) presence of blood in the stools after 3 days upon a meat-free diet; (c) presence of occult blood within the gastric contents.

Of the 100 patients studied evidence of blood loss was observed in 42 cases (42%). The arithmetical mean of the serum protein in this group is 6.1 grams per cent. In the other 58 per cent of the series that did not present any evidence of blood loss the arithmetical mean of the serum protein concentration is 6.1 grams per cent (8). The difference between these two groups is not statistically significant; hence it can be concluded that bleeding does not contribute significantly to the low level of the serum protein in this series of patients.

Abnormalities in amino acid metabolism. The possibility presents itself that amino acids are not absorbed properly or that after they are

control animals and the animals previously transfused showed considerable variation in response to acute plasma protein loss. As has been stated some of the dogs quickly added as much as 10 to 11 grams of protein to the circulation others none at all. The average response by control and previously transfused dogs was not significantly different.

It would appear that rapid influx of plasma protein to the blood stream following bleeding depends upon at least 3 factors (1) acute need (2) availability of protein in stores and (3) the original concentration of protein in the plasma. Since the acute need for protein was standardized in all our animals and since there was no consistent relationship in our experiments between original plasma concentration and the amount of protein returned to the plasma variations in response are attributed in a large part to variations in availability of suitable stored plasma protein. Inasmuch as there was little difference in response to hemorrhage between our control and transfused dogs, it follows that the transfusions given prior to bleeding probably did not add protein to protein stores in such a form that it could be called upon in case of acute need.

CONCLUSIONS

1 Results of rapid sublethal hemorrhage in normal dogs and in dogs previously transfused with whole blood have been presented.

2 A blood transfusion given a few hours before sublethal hemorrhage in normal dogs did little to influence the posthemorrhagic response except to supply an extra number of red blood cells and possibly a small fluid reserve.

3 Evidence is presented to support the existence of plasma protein stores.

4 The protein that was given with a blood transfusion to a normal dog quickly left the circulation. There is reason to believe that part of it at least entered plasma protein depots.

5 When a previously transfused animal was subjected to an acute sublethal hemorrhage as a rule only a small portion of the needed plasma protein was added promptly to the circulation following the hemorrhage.

6 It seems probable therefore that the plasma protein which disappeared from the circulation following transfusion of normal dogs did not in most cases enter protein stores in such a form as to be available for immediate recall to the circulation following rapid sublethal hemorrhage.

THE NATURE OF POSTOPERATIVE HYPOPROTEINEMIA IN PATIENTS WITH GASTROINTESTINAL CANCER

IRVING M ARIEL, M D., Minneapolis, Minnesota

PATIENTS with gastrointestinal cancer frequently present variable degrees of emaciation and cachexia. Because of the high incidence and great mortality from gastrointestinal cancer, a study was instituted to investigate some of the metabolic abnormalities that might exist. This report deals with the incidence and degree of hypoproteinemia in patients with gastrointestinal cancer and emphasizes the effect of surgery upon certain phases of nitrogen metabolism

PREOPERATIVE PLASMA PROTEIN CONCENTRATION IN PATIENTS WITH GASTRIC CANCER

One hundred patients with gastrointestinal cancer have been studied as to the state of their serum proteins. Serum protein for normal individuals has been found to range from 6.5 to 7.4 grams per cent. The average is 6.9 grams per one hundred cubic centimeters with a standard deviation of ± 0.47 gram per cent. In sharp contrast the average serum protein concentration in patients with gastrointestinal cancer is 6.2 grams per cent with a standard deviation of ± 0.67 gram per cent. Of the 100 patients examined 59 were found to have abnormally low levels (Charts 1 and 2) (8).

The cause of hypoproteinemia is not entirely clear. Several possibilities present themselves namely (1) deficient diets (2) repeated hemorrhage (3) a defect in the absorption of amino acids (4) increased catabolism of the protein or (5) some metabolic abnormality which prevents the synthesis of serum proteins.

Dietary deficiency. In an attempt to ascertain the role played by a deficient dietary intake in the production of hypoproteinemia the patients were divided into five groups

according to the degree of dietary deficiency. The mean serum protein level and the standard deviation were computed for each group.

The distribution of the serum protein determinations was plotted against variations in diet to show what effect, if any, dietary intake has on the serum protein level. Analysis of the data reveals no statistically significant difference between the means of the different groups which gave evidence of dietary deficiency. All protein values were significantly lower than normal (Chart 3).

It thus becomes apparent that variations in the degree and duration of dietary deficiency do not contribute by themselves significantly to the incidence and degree of hypoproteinemia in patients with gastric cancer.

Relationship of bleeding to hypoproteinemia. Bleeding is an important factor which might be responsible for an abnormal erythron or a low plasma protein concentration. In this series a patient was considered to present evidence of blood loss if he fulfilled any one of the following criteria: (a) history of blood loss (melena, hematemesis, etc.) within 6 months previous to his admission; (b) presence of blood in the stools after 3 days upon a meat-free diet; (c) presence of occult blood within the gastric contents.

Of the 100 patients studied, evidence of blood loss was observed in 42 cases (42%). The arithmetical mean of the serum protein in this group is 6.1 grams per cent. In the other 58 per cent of the series that did not present any evidence of blood loss the arithmetical mean of the serum protein concentration is 6.2 grams per cent (8). The difference between these two groups is not statistically significant; hence it can be concluded that bleeding does not contribute significantly to the low level of the serum protein in this series of patients.

Abnormalities in amino acid metabolism. The possibility presents itself that amino acids are not absorbed properly or that after they are

Parts of this study were performed at Memorial Hospital, New York, New York.

The heavy embroken line represents the mean of each group and the area between the broken lines represents the values between the plus and minus standard deviations from the mean.

absorbed they can not be utilized in a normal manner. This has been substantiated. The ingestion of 25 grams of aminoacetic acid revealed that in 6 controlled subjects the maximum absorption of the compound occurred within the first hour. In contrast to this, in 6 patients with gastrointestinal cancer the peak of absorption was considerably delayed in all. The delayed absorption of the amino

acid apparently does not depend merely on the presence of organic gastrointestinal disease for a normal rate of absorption was noted in one patient with atrophic gastritis, in one patient with multiple gastric ulcers, and also one patient with gastric Boeck's sarcoid. These data indicate that the abnormality of absorption may be intimately linked with the presence of cancer (9) (Chart 4). After resection of the cancer improvement of absorption occurs (Chart 5).

The following experiments indicate that in addition to the defective absorption of the amino acid there exists also abnormalities of their metabolism.

a. The ingestion of 25 grams of aminoacetic acid raised the average concentration of serum amino acids in normal individuals by 2.9 milligrams per 100 cubic centimeters. The average increase in the serum of 6 patients with gastrointestinal cancer was 6.6 milligrams (Chart 4). This high level of amino acids in the serum of patients given aminoacetic acid orally has been demonstrated to indicate inability of the liver to utilize that compound at a normal rate (9).

b. Following the intravenous administration of 75 milligrams per kilogram body weight

Chart 2. Frequency polygon of total serum protein concentration of patients with gastric cancer compared with normal individuals. — gastric cancer — normal individuals.

Chart 5 A scatter diagram of total protein concentration per 100 cubic centimeters of serum in patients with gastric cancer referred to degrees of dietary deficiency. The heavy unbroken line represents the mean of each group and the area between the broken lines represents the values between the plus and minus standard deviations from the mean.

aminoacetic acid the analyses of the urinary output of creatine and creatinine in both normal controls and patients with gastrointestinal cancer reveals a marked increase in the amount of creatine and creatinine excreted by 9 normal individuals and 7 patients with benign gastrointestinal disease. The average increase in the normal group was 53.5 milligrams of creatine and 70 milligrams of creatinine and for the 7 patients with benign gastrointestinal lesions, 27.5 milligrams of creatine and 68.5 milligrams of creatinine.

In sharp contrast to these findings there was no increased creatine or creatinine in 19 patients with gastrointestinal cancer (2). This fact suggests that glycine which is the precursor for the formation of creatine so necessary for muscle metabolism is not utilized in its normal manner. The muscular weakness noted so frequently in patients with gastrointestinal cancer possibly could be the result of inability of these patients properly to synthesize creatine from glycine.

Hepatic dysfunction. The hypoproteinemia might conceivably be a manifestation of

hepatic dysfunction. Since it has been demonstrated that patients with gastrointestinal cancer suffer a high incidence of hepatic dysfunction (3) a comparison was made of the plasma protein concentration of 100 patients with gastrointestinal cancer and of 20 patients with hepatic cirrhosis. The data demonstrate that the degree of plasma protein depletion in patients with gastric cancer was far more severe than in those with hepatic cirrhosis (Chart 6). The albumin protein was the fraction that was depleted always (Chart 7).

Protein catabolism. Studies of the fecal nitrogen output of patients with gastrointestinal cancer revealed no dissimilarity to other groups of patients. The average fecal output is approximately 1 gram of nitrogen per day. Furthermore the urinary nitrogen of these patients while at rest is not in excess of that of control groups of persons (8). These data demonstrate that there is no increased catabolism of proteins to account for the depleted state.

The data thus far presented demonstrate that patients with gastrointestinal cancer suf

Chart 6 Frequency polygon of total serum protein concentration of patients with gastric cancer compared with patients with hepatic cirrhosis. — gastric cancer — hepatic cancer

who were submitted to surgical procedures similar to those to which were subjected the patients with gastrointestinal cancer. The results obtained in the patients with non-neoplastic gastrointestinal disease form an interesting contrast to those of the patients with cancer.

The preoperative concentration of serum protein in the patients with benign gastrointestinal disease ranged from 5.9 to 7.1 grams, and averaged 6.54 grams per cent.

When these individuals were subjected to surgery their serum protein levels fell in 6 instances from 0.1 to 0.3 gram, average 0.18

gram per cent. In one, no change in the serum protein concentration was noted, and in the remainder these concentrations increased by from 0.1 to 0.4 gram per cent in that period. However although no significant decrease in the concentrations of serum protein was observed in these individuals, nevertheless, they excreted from 5.3 to 13.8 grams of urinary nitrogen per day (average 8.90 grams per day) during the first five postoperative days. It is to be noted that these amounts of urinary nitrogen are the same as those excreted by the patients with gastrointestinal cancer who did develop hypoproteinemia. As in the latter group no correlation could be made between the postoperative levels of serum protein and the amounts of urinary nitrogen excreted.

The second control group of patients investigated were 9 women subjected to gynecologic surgery. It was believed that this study would provide data of the effects on protein catabolism of intra abdominal operations other than those on the gastrointestinal tract. The preoperative concentrations of serum protein of these 9 patients ranged from 5.9 to 7.6 grams and averaged 6.61 grams per cent. Of these 4 had abnormally low levels. Within 5 days after operation the concentration of serum protein fell in 5 from 0.1 to 1.1 grams. The average decrease of these 5 patients was 0.38 gram per cent. The concentration of serum protein did not change in 1 instance, and increased from 0.1 to 0.2 gram per cent in the remaining 3 patients.

Chart 7 The albumin and globulin concentrations in the serum of patients with gastric cancer

During the first 5 postoperative days the average daily amounts of nitrogen excreted by the patients with gynecologic disorders ranged from 3.24 to 10.35 grams and averaged 7.04 grams. As in the other 2 groups of patients who were studied, no correlation could be made between the amounts of urinary nitrogen which were excreted and the amounts by which the serum protein concentrations decreased.

It is of considerable importance to note however that although the 2 control groups of patients lost an average of 7.04 and 8.90 grams of urinary nitrogen per day after operation the patients with gastrointestinal cancer excreted a comparable quantity of nitrogen, 8.96 grams per day. The average maximum change in the concentration of serum protein in the patients with gastrointestinal cancer, however, was 0.81 gram per cent, whereas the concentration of serum protein in the 2 control groups decreased only 0.18 and 0.38 gram per cent.

The maximum serum protein drop occurred on the fourth postoperative day. Despite rigorous attempts at re-establishing a normal plasma protein level the plasma proteins remained low during the 29 day period following

Chart 8. Frequency polygon of total serum protein concentration of patients with gastric cancer compared with a group of patients in whom the cancerous stomach previously had been resected. — gastric cancer — hepatic cancer

surgery that the patients were studied (Chart 10).

The findings indicate that not only are the concentrations of serum protein in patients with gastrointestinal cancer low before operation but those levels now have been found to fall to still further abnormally low limits after operation. There is now reason to believe that

Chart 9. Frequency polygon of total serum protein concentration of patients with gastric lesions and of patients with benign duodenal lesions.

TABLE I—EFFECT OF OPERATION UPON THE SERUM PROTEIN CONCENTRATION IN PATIENTS WITH DIFFERENT DISEASE PROCESSES AND THEIR EXCRETION OF URINARY NITROGEN

Patient's ill	Number of patients	Preoperative serum protein concentration gm. per cent	Average maximum drop in serum protein level during first 3 postoperative days—gm. per cent	Per cent of patients whose serum protein dropped after operation	Average daily urinary nitrogen during first 3 days postoperative gm.
Gastrointestinal cancer	47	6.3	3	84	2.96
Non-neoplastic disease of the gastrointestinal tract	9	6.34	1.8	67	2.90
Gynecological disorder	9	6.8	2.8	55	2.81

the hypoproteinemic state developed after operation chiefly is responsible for the high incidence among these patients of wound disruption, disturbed electrolyte equilibrium (6) adynamic ileus and gastrointestinal and peripheral edema. Because of the development of these serious postoperative complications the existence of hypoproteinemia in patients with gastrointestinal cancer becomes of considerable importance.

Although both the patients with gastrointestinal cancer and those of the 2 groups used

as controls all excreted comparably equal amounts of urinary nitrogen after operation, only the first group of individuals sustained considerable reductions of their serum protein levels. The explanation for this observation probably is that (a) the tissue protein stores of patients with cancer of the gastrointestinal tract are depleted and therefore cannot restore the serum protein concentrations to their preoperative levels and (b) the ability of these individuals to fabricate serum protein is impaired.

Chart 10. Postoperative serum protein alterations in patients with gastric cancer. The small black squares represent individual determinations. The curve demonstrates the average daily postoperative fluctuation of the serum protein concentration.

RELATIONSHIP OF LIVER PROTEIN TO PLASMA PROTEIN CONCENTRATION

From evidence recently presented a decreased concentration of serum protein has been found associated with depletion of tissue proteins (12).

It has been observed that the livers of fasted animals are depleted of proteins with great rapidity (4) and that when animals are maintained on high protein diets all the protein fractions of their livers increase (11). These observations suggest that the liver may store proteins and that those stores might be abnormally reduced in the hypoproteinemic patients.

To note if any correlation existed between the protein concentration of the liver and the depleted plasma protein content, chemical analyses of the livers of 12 patients with gastro-

intestinal cancer were performed. The data are summarized in Table II.

The concentrations of proteins in the normal human liver are not known and so not available for purposes of comparison. One may hazard perhaps a comparison of the values obtained with those of animal liver tissue. The total protein in the liver of the rat has been found to average 15.5 grams the albumin 2.1 grams and the globulin 13.4 grams per cent. In the dog liver the average total protein content has been found to be 17.5 grams per cent.

The total hepatic protein in 12 patients with gastrointestinal cancer ranged from 12.9 to 17.95 and averaged 16.17 grams per cent. The albumin contents averaged 5.10 grams and varied from 3.2 to 8.05 grams per cent, and the globulin averaged 11.0 and ranged

TABLE I—EFFECT OF OPERATION UPON THE SERUM PROTEIN CONCENTRATION IN PATIENTS WITH DIFFERENT DISEASE PROCESSES AND THEIR EXCRETION OF URINARY NITROGEN

Female	33	42 (127%)	2 (6%)	14 (42%)

The ability to control fully the side effects of beta methylcholine urethane by the administration of atropine (5) makes it a more desirable drug than other choline esters. Starr and Ferguson (11) have given very complete data concerning the drug and its action in various normal and abnormal conditions.

The drug was given orally to the first group of patients in doses ranging from 4 milligrams every 4 hours up to 10 milligrams every 30 minutes for three doses as indicated by individual response. The results were poor and have not been included in this report. Subcutaneous administration has been much more effective and the drug is now given exclusively by this route. The most efficient results are obtained by giving 5 milligram doses at 30 minute intervals for three injections. If the patient voids satisfactorily after any one of the three administrations the drug is discontinued. The patient is catheterized if the third 5 milligram dose does not produce urination and then the drug is repeated as indicated later. We observed each case of the recorded group continuously throughout each procedure. The drug is probably too potent for safe

administration by the intravenous or intramuscular route in the treatment of postoperative urinary retention.

RESULTS

We have recorded the results obtained in 76 consecutive unselected cases of postoperative urinary retention in which the drug was administered subcutaneously as outlined herein. Other methods of treatment had been tried without success in all except 12 patients and the time interval following the operative procedure varied from 6 hours to the eighth postoperative day. Dosages as large as 10 milligrams every 30 minutes for three injections were given subcutaneously in some of the earlier patients but in some instances the side actions of the drug were rather uncomfortable and the clinical results were only slightly more favorable. Since accumulating the data recorded in Tables I, II, and III we have administered the drug in about 150 additional cases with comparable results. There are 43 male and 33 female patients in the detailed recorded groups.

Tables I and II list the patients as to the type of operative procedure performed previous to the complication of postoperative retention and group the cases in three categories according to the results. These latter include successes, partial successes, and failures.

None of the patients classified as the successful group had to be catheterized. Forty-six patients voided spontaneously after subcutaneous administration of 5 milligrams of beta methylcholine urethane repeated at 30 minute intervals for three times when necessary. Seventeen of the 46 patients voided after being given 5 milligrams of the drug and in the remaining 29 it had to be repeated once or twice. The drug was routinely repeated if the bladder could be percussed or if the patient remained uncomfortable because of bladder distention following the first or second dose. The number of successes was higher in the male group.

In the patients classified as partially successful one series of beta methylcholine urethane was given as outlined previously and the individual did not void. The patient was then catheterized. Eight to 10 hours later the pro-

THE USE OF BETA-METHYLCHOLINE URETHANE IN POSTOPERATIVE URINARY RETENTION

FRED K. GARVEY M.D., F.A.C.S., MEDFORD C. BOWMAN M.D. and
WILLIAM L. ALSOBROOK, M.D. Winston-Salem North Carolina

CONSIDERABLE search has been made for an effective drug to use for the treatment of postoperative urinary retention. Time honored methods are unreliable and most of the drugs which have been used have proved inadequate. We have found beta methylcholine urethane beneficial in a large percentage of these cases although it is not a final solution to the problem.

Postoperative urinary retention is that condition occurring following an operation in which the patient cannot void despite a full bladder normal kidney function and the absence of any organic obstruction. Normally the urinary bladder fills passively and empties under voluntary control. It is partly under voluntary control and is richly supplied by three sets of nerves. The sympathetic nerve supply is through the presacral and hypogastric nerves the stimulation of which relaxes the bladder wall and contracts the internal sphincter. The parasympathetic nerve supply is by way of the nervi erigentes upon stimulation of which relaxation of the external sphincter and contraction of the detrusor result. The pudendal nerve produces voluntary control of the external sphincter muscle and other perineal accessory muscles of urination. The desire to void depends upon intravesical pressure and not necessarily on the amount of urine present in the bladder. The average male bladder capacity is about 300 cubic centimeters and the female bladder capacity slightly less. The desire to void arises with a urinary bladder volume of 130 to 150 cubic centimeters. Contraction of the detrusor muscle, which constitutes the entire bladder musculature and the relaxation of the sphincters bring about emptying of the bladder. The

trigonal muscle shortens and helps open the sphincters.

MATERIAL AND METHODS

Since the pioneer work of Dale, in 1914, it has been known that drugs belonging to the choline series mimic the effects produced by stimulation of the parasympathetic nervous system. Dale introduced the term 'parasympathomimetic' to describe these properties of choline derivatives. It has also been observed that atropine annuls the parasympathetic effects of choline derivatives (10).

Acetyl-beta methylcholine (methylol) (2, 3, 4, 7) and carbaminoyl-choline (doryl) (6, 9) have been the most widely used choline derivatives for their effects on the urinary bladder. Methylol is not stable and is quickly destroyed by the body fluids. Doryl has been found to be stable but possesses a very strong nicotinic action. We have had relatively little clinical experience with either of these drugs.

Carbaminoyl-beta methylcholine chloride (beta methylcholine urethane) was synthesized by Major in 1935 at the suggestion of Simonart (8). The empirical formula is $C_{11}H_{19}N_2O_2Cl$ and the structural formula is

The pertinent quantitative solubilities are 1 gram in 0.6 cubic centimeter of water at room temperature and 1 gram in 12.5 cubic centimeters of 95 per cent ethanol at room temperature. The aqueous solution is very stable. The therapeutic and toxic effects of this drug are considerably less than those with doryl. This drug at present appears to be the most promising of the choline derivatives in the treatment of functional urinary retention.

From the Departments of Urology and Surgery, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, North Carolina.

The ability to control fully the side effects of beta methylcholine urethane by the administration of atropine (5) makes it a more desirable drug than other choline esters. Starr and Ferguson (11) have given very complete data concerning the drug and its action in various normal and abnormal conditions.

The drug was given orally to the first group of patients in doses ranging from 4 milligrams every 4 hours up to 10 milligrams every 30 minutes for three doses as indicated by individual response. The results were poor and have not been included in this report. Subcutaneous administration has been much more effective and the drug is now given exclusively by this route. The most efficient results are obtained by giving 5 milligram doses at 30 minute intervals for three injections. If the patient voids satisfactorily after any one of the three administrations the drug is discontinued. The patient is catheterized if the third 5 milligram dose does not produce urination and then the drug is repeated as indicated later. We observed each case of the recorded group continuously throughout each procedure. The drug is probably too potent for safe

administration by the intravenous or intramuscular route in the treatment of postoperative urinary retention.

RESULTS

We have recorded the results obtained in 76 consecutive unselected cases of postoperative urinary retention in which the drug was administered subcutaneously as outlined herein. Other methods of treatment had been tried without success in all except 12 patients and the time interval following the operative procedure varied from 6 hours to the eighth postoperative day. Dosages as large as 10 milligrams every 30 minutes for three injections were given subcutaneously in some of the earlier patients but in some instances the side actions of the drug were rather uncomfortable and the clinical results were only slightly more favorable. Since accumulating the data recorded in Tables I, II, and III, we have administered the drug in about 150 additional cases with comparable results. There are 43 male and 33 female patients in the detailed recorded groups.

Tables I and II list the patients as to the type of operative procedure performed previous to the complication of postoperative retention and group the cases in three categories according to the results. These latter include successes, partial successes, and failures.

None of the patients classified as the successful group had to be catheterized. Forty-six patients voided spontaneously after subcutaneous administration of 5 milligrams of beta methylcholine urethane repeated at 30 minute intervals for three times when necessary. Seventeen of the 46 patients voided after being given 5 milligrams of the drug and in the remaining 29 it had to be repeated once or twice. The drug was routinely repeated if the bladder could be percussed or if the patient remained uncomfortable because of bladder distention following the first or second dose. The number of successes was higher in the male group.

In the patients classified as partially successful one series of beta methylcholine urethane was given as outlined previously and the individual did not void. The patient was then catheterized. Eight to 10 hours later the pro-

TABLE II.—PROCEDURES RESULTING IN VOIDING FOLLOWING THE SUBCUTANEOUS ADMINISTRATION OF BETA METHYLCHOLINE URETHANE IN 76 CASES OF POSTOPERATIVE URINARY RETENTION

Procedure	No. of cases voiding	No. of cases not voiding	Per cent	Classification
A. Single 5 mgm. dose	17		1%	
B. Two or three 5 mgm. doses at 30 minute intervals	19		26%	
Total	46		66%	Successes
C. Three 5 mgm. doses at 30 minute intervals, followed by catheterization; drug repeated if necessary			14%	
D. Procedure C repeated once	7		9%	
Total			23%	Partial successes
E. Failure of the above procedures and some supplementary method used			1%	Failures

cedure was repeated if the patient was uncomfortable or if he desired to void and could not. The partial success cases are classified arbitrarily as those in which the drug-catheterization therapy was instituted one and two times. A total of 19 cases make up this group. Twelve of the 19 patients were catheterized once and 7 were catheterized twice and the drug was given as indicated.

Eleven patients in which the beta methylcholine urethane-catheterization procedure was repeated more than twice and in which some other method of treatment was started are classified as failures. We have also included in this group of 21 cases 4 patients who because of uncomfortable side actions of the drug preferred catheterization or some other mode of treatment to further administration of the drug.

The actions and side actions of beta methylcholine urethane as we observed them are summarized in Table III. These are listed under six general headings—circulatory, urinary, gastrointestinal, glandular (secretory), respiratory, and visual. Doses of 5 milligrams each repeated at 30 minute intervals as outlined previously did not cause any of the patients to have any alarming side effects although a few did become rather uncomfort-

able after the second or third dose. It was not necessary to give atropine to any of this group of patients to relieve the side actions but we did give 0.9 milligram (1/75 gr.) subcutaneously to each of 10 patients to observe its effect and found that the parasympathetic actions of beta methylcholine urethane were relieved completely in 10 to 15 minutes by the atropine. Atropine was occasionally given to apprehensive patients when larger doses than 5 milligrams of urethane were administered and in no case did atropine fail to counteract the side actions completely. Flushing (80%) sweating (80%) and bladder pain urethral pain or both (92%) were the effects most frequently encountered and they usually occurred in this sequence. All patients who voided successfully following administration of the drug had bladder pain urethral pain or both. The symptoms of respiratory and visual side effects were usually elicited only on direct questioning of the patient. There was no significant change in the pulse rate and the systolic blood pressure did not fall more than 8 points in any patient. The drug proved to be a useful adjunct to the treatment of postoperative intestinal distention in 26 (35%) patients who passed flatus following the administration of the drug.

DISCUSSION

It is, of course, difficult to evaluate accurately the effectiveness of any drug or procedure in the treatment of postoperative urinary retention for psychogenic factors play a large role in the problem. It has been repeatedly observed that functional retention is seldom seen in the postoperative mentally deficient patient. The value of beta methylcholine urethane is exhibited in its minimal toxic side reactions and in the fact that atropine will completely neutralize these side actions should they become excessive.

We have previously outlined what we consider the most effective method and drug dosages. The patient, if female, should be placed on a bedpan at the time of each administration or very shortly afterward. With male patients a urinal should be immediately available at the time of drug administration. The drug is usually effective in 5 to 15 minutes. It is probably more effective in male patients because of the greater simplicity of the urinal over the bedpan in voiding. The drug is given preferably on an empty stomach, before meals and more than 2 hours after eating or taking fluids orally. If the drug is given immediately after eating about one-third of the patients will develop nausea and vomiting. Beta methylcholine urethane seldom has to be repeated more than two or three times after the patient has voided one time and once it has been successful in emptying the bladder it is practically always successful on subsequent administration. We have observed no local reactions when the drug is given subcutaneously. One 5 milligram dose was inadvertently given intramuscularly. The patient urinated 700 cubic centimeters within less than 4 minutes and had rather accentuated and distressing side actions but these were relieved within 10 minutes by the prompt administration of 1/75 grain (0.9 mgm) of atropine subcutaneously. Better results are obtained if the drug is not given to apprehensive patients. We personally administered the drug and observed all the patients in the present group but in later cases left the administration to the supervising nurse each dose being ordered separately and the procedure varied according to the effect of the preceding dose. The side actions, if pre-

sent, are usually more pronounced with the first series and decrease with each succeeding series. Adequate fluid intake is of great importance especially after the drug has been effective one time. The drug was found to be very effective in cases in which the patient was having urinary overflow or voiding small amounts spontaneously. The type of anesthetic agent used for the operative procedure apparently had little effect on the results obtained.

The mechanical effects of the operative procedure doubtless affect the results to be expected from any parasympathomimetic drug used in the treatment of functional postoperative urinary retention. Abdominal operations affect the action of the abdominal musculature used in aiding the voiding act. Our highest incidence of partial successes was in the group of patients who had anterior colporrhaphy, in which there was trauma and probably actual constriction of the tissues surrounding the urethra. The drug cannot be expected to act as successfully in the case of patients in whom part of the nerve supply to the urinary bladder is destroyed.

Beta methylcholine urethane is contraindicated in the presence of vesical neck obstruction, asthma, and hyperthyroid conditions. It would not seem wise to use it in patients after recent intestinal anastomoses, obstructive resections or other intestinal procedures where increased peristalsis might prove harmful. It should not be used in patients with coronary sclerosis, known heart disease, or in elderly individuals in whom tachycardia and a drop in blood pressure might lead to myocardial damage or infarction.

SUMMARY AND CONCLUSIONS

1. Beta methylcholine urethane, a choline derivative, has been used in the treatment of 76 consecutive unselected cases of postoperative functional urinary retention.

2. The drug is stable, shows minimal side actions, and these can be completely counteracted by the use of atropine.

3. The drug was successful in relieving the urinary retention in 46 (60%) of the cases and partially successful in 19 (25%). Eleven (15%) cases were classified as failures.

4 The contraindications to the use of the drug for postoperative retention are vesical neck obstructions, asthma, hyperthyroidism recent intestinal anastomoses elderly individuals except cautiously in small doses and in individuals with coronary sclerosis or known heart disease.

THE EFFECT OF SULFATHALIDINE ON THE BLEEDING AND CLOTTING TIME OF THE BLOOD AND PROLONGATION REDUCTION BY THE ADMINISTRATION OF VITAMIN K

LOUIS T WRIGHT M.D., F.A.C.S., FRANK R. COLE, M.D., and
LYNDON M. HILL, Jr., M.D., New York, New York

SULFATHALIDINE or phthalylsulfathiazole was introduced in 1943 by Poth and Ross (11). The antibacterial action of this compound effects a considerable reduction of the gram negative bacteria of the bowel, both anaerobic and aerobic organisms being susceptible. Sulfathalidine has from two to four times greater bacteriostatic activity than succinylsulfathiazole as indicated by the effect on coliform organisms.

Allen found that increased bleeding had occurred after 4 or 5 days of sulfasuxidine administration in one fifth of the patients with a carcinoma of the colon. Poth (8,9,10) observed an increase of bleeding in an occasional patient but stated that when sulfasuxidine was used the incidence of bleeding was not high.

Firor reported that in 2 patients with large ulcerating carcinomas of the colon the administration of succinylsulfathiazole had to be discontinued because of alarming hemorrhage. Sanders and Halperin reported postoperative hemorrhages accompanied by a low prothrombin level in 2 patients following the use of sulfasuxidine, and in both cases vitamin K intravenously administered stopped the hemorrhage. In both of these cases, the prothrombin level had been normal prior to the administration of sulfasuxidine. They believed that the marked reduction of vitamin K synthesizing colonic bacteria brought about by sulfasuxidine was partly responsible for the hemorrhagic phenomenon. They stated that since then they have routinely given synthetic vitamin K by mouth to all patients receiving sulfasuxidine.

Kornberg and Seberell studied the production of vitamin K deficiency in rats with sulfathalidine.

From the Surgical Service of Harlem Hospital.

pyrazine sulfadiazine sulfathiazole, sulfaguanidine and succinylsulfathiazole and they found all of these drugs effective in varying degrees in producing rapidly and consistently a severe vitamin K deficiency with a significant prolongation of the clotting time of whole blood and with massive hemorrhages. They found that the order of effectiveness of the sulfonamide compounds used in the production of vitamin K deficiency was in direct proportion to their effectiveness in regard to bacteriostasis of coliform organisms in the intestines of the animals.

In man bacteria, one natural source of vitamin K, are of great practical importance. Almquist has reported that cultures of numerous organisms such as *Staphylococcus aureus*, *Escherichia coli*, *Bacillus subtilis* are all rich in vitamin K. The large amount of vitamin K formed and constantly absorbed by coliform organisms in the human bowel probably explained the difficulty with which hemorrhagic disease is produced in mammals by feeding a vitamin K deficient diet and the rarity with which simple nutritional deficiency of vitamin K is observed in man, as shown by Kark and Lozner. Kolmer states that hypoprothrombinemia may be caused by actual lack of vitamin K due to temporary sterility of the intestinal tract.

With these facts in mind and because clinically we have observed increased bleeding with the use of sulfathalidine, although Poth (8,9,10) and Allen have reported no increase we decided to observe the bleeding and clotting times of all patients receiving sulfathalidine. Poth has reported bleeding and clotting times to be normal when sulfathalidine was used. We determined the bleeding and clotting time of patients before sulfathalidine therapy

was started and after the patient had been given sulfathalidine for 5 days. The bleeding time (13) was determined by a puncture wound of the finger. The time of the appearance of the first drop of blood was noted. Each drop as it formed was removed with filter paper. The time that the bleeding stopped was noted. The time interval between the appearance of the first drop and the removal of the last represented the bleeding time.

Coagulation time (3) was determined in the following manner. Several drops of blood from a puncture wound of the finger were placed on 3 glass slides. At intervals of 15 seconds a needle was drawn through one of the drops, when shreds of fibrin clung to the needle and were dragged along by it, coagulation had taken place and this time was then noted as coagulation time.

In 71 patients in the series bleeding and clotting time was observed before and after

the administration of sulfathalidine therapy and the results are given in Table I. The first 5 patients received a dosage of 5 grams of sulfathalidine per day and the rest of the patients a dosage of $\frac{1}{4}$ gram of sulfathalidine per kilo in 6 divided doses.

In 29.5 per cent of the patients given sulfathalidine therapy there was an increase in the bleeding time of more than 2 minutes over the level before the drug was started and in 53.5 per cent of the patients there was an increase of over 2 minutes in the clotting time. In 70.5

TABLE II.—INCREASE IN BLEEDING AND CLOTTING TIME IN 9 CASES

	Increase in bleeding time	Increase in clotting time
Over 1 minute	5	—
Over 2 minutes	3	4
Over 3 minutes	1	1
Over 4 minutes	—	2
Over 6 minutes	—	1
Over 8 minutes	—	1

				3	0	4	45

per cent of the patients there was an increase in the bleeding time of at least 1 minute over the time before sulfathalidine administration was started, and in 78.8 per cent of the patients receiving sulfathalidine ingestion there was an increase in the clotting time of over 1 minute.

Allen as previously quoted stated that in one fifth of the patients with carcinoma of the colon he found that increased bleeding occurred after 4 to 5 days of sulfasuxidine administration. With sulfathalidine therapy we found an increase in the bleeding and clotting time in all 9 patients with carcinoma of the large bowel as shown in Table II.

After we started to administer vitamin K to all patients receiving sulfathalidine therapy we obtained the following results. In 7 patients with carcinoma there was no change in the bleeding and clotting time of 6. In 1 patient there was observed the following change: the bleeding time increased from 1 minute 45 seconds to 3 minutes, and the clotting time from 3 minutes 15 seconds to 6 minutes, 15 seconds.

We then started to give vitamin K, 5 milligrams twice per day to the patients receiving sulfathalidine therapy, and in this group of 30 patients there was no change in the bleeding or clotting time of 22 patients or in only 8 cases was the bleeding and clotting time elevated and then by only 1 minute. Thus there was an increase in the bleeding time in 26.6 per cent of the patients who received vitamin K and sulfathalidine as compared to 70.5 per cent of the patients who did not receive vitamin K, and the clotting time was elevated in 26.6 per cent of the cases as compared to 78.8 per cent.

A detailed analysis of the results which were obtained in these cases is to be found in Table III.

CONCLUSIONS

From our observations of the bleeding and clotting time of 71 patients the following conclusions were reached:

1. When administered in therapeutic doses sulfathalidine increased the bleeding and clotting time in these cases.

ONE STAGE END-TO-END ANASTOMOSIS OF THE COLON

An Analysis of the Complications in 79 Cases with a Comparison of Open and Aseptic Types of Anastomoses

GEORGE P ROSEMOND M.D., F.A.C.S., W EMORY BURNETT, M.D., F.A.C.S.
and FRANCIS N COOKE, M.D., Philadelphia, Pennsylvania

ONE hundred fifteen years ago, a French surgeon of Lyons after experimental work on dogs under took the resection and one stage end to-end anastomosis of the sigmoid colon in a patient afflicted with cancer. The patient survived the operation and lived until he succumbed to recurrence 1 year later. This occurred in the year 1833. Reports of this operation reached the ears of the members of the Royal Academy of Medicine in Paris and in March of the year 1844 they dispatched a commission to Lyons in order to observe and report to the Academy the works of this Reybard of Lyons. In July of that year the commission Messrs Blandin Bevard and Jobert de Lambelle (27) made their report. M Reybard lacking suitable clinical material had demonstrated his technique on dogs. In all 7 dogs were used in the demonstration. The results of this experiment were not good. Post mortem examinations revealed that adequate healing had not taken place between the ends of the anastomosed intestines. Some specimens had not healed at all and in others large fistulous openings were apparent. So the commission concluded since the procedure was so unsuccessful in experimental animals was there any reason to believe that it would be more successful in man? The Academy thought not and so the one stage end to-end anastomosis of the colon as a method of treatment of carcinoma of the bowel was rejected by the Royal Academy of Medicine in Paris.

The history of colon surgery might have been entirely different had Reybard been acquainted with the work of one of his contemporaries

that of Antoine Lembert. M Lembert reported to the surgical section of the Royal Academy of Medicine in Paris his experimental work on dogs in which he had devised a method of suture which allowed the intestinal wound edges to heal rapidly and with excellent approximation. Altogether he had operated upon 5 dogs. All 5 dogs lived. He further observed that the operative procedure in most of the dogs scarcely interrupted their normal habits of eating and elimination. This report was made January 26, 1826. This method of suture is the basis of our modern technique in intestinal surgery. We speak of it as the Lembert suture.

Since this early report on the works of M Reybard to the French Royal Academy of Medicine surgery of the colon has passed through many painful phases. Although colostomy was known and had been performed by Pillare (10) in 1776 and successfully by Duret (10) in 1793 surgical resection of the diseased colon had not been reported. In fact during this period, the only relief offered patients suffering from cancer of the distal colon according to Thomas Copeland was the cauterization of the very painful hemorrhoids which developed as a consequence of the obstructed circulation in the parts. Copeland described the late stage of the disease very accurately. He states "introduction of the finger into the rectum will be opposed by a hard ring of cartilagenous feel composed of the diseased inner ring of the intestine." He also observed that despite vigorous treatment of the piles the true nature of the disease went unrecognized. According to Dinnick whose excellent and very thorough work, *The Origin and Evolution of Colostomy* was published in 1934 it was not until the middle of the 19th century that colostomy became widely used

From the general surgery service Temple University Hospital, and from the surgical service of Dr. W. W. Babcock, Temple University Hospital.

Abdication of thesis submitted in March, 1943, by Dr. Cooke as required for the degree of M.S. in Surgery.

2 The administration of vitamin K reduced this prolongation of the bleeding and clotting time in most instances.

3 All patients who receive sulfathalidine preoperatively and postoperatively should at the same time, receive vitamin K in order to prevent a vitamin K deficiency and an increase in the bleeding and clotting time.

ONE STAGE END-TO-END ANASTOMOSIS OF THE COLON

An Analysis of the Complications in 79 Cases with a Comparison of Open and Aseptic Types of Anastomoses

GEORGE P ROSEMOND M.D., F.A.C.S., W EMORY BURNETT, M.D., F.A.C.S.
and FRANCIS N COOKE, M.D., Philadelphia, Pennsylvania

ONE hundred fifteen years ago a French surgeon of Lyons after experimental work on dogs under took the resection and one stage end to-end anastomosis of the sigmoid colon in a patient afflicted with cancer. The patient survived the operation and lived until he succumbed to recurrence 1 year later. This occurred in the year 1833. Reports of this operation reached the ears of the members of the Royal Academy of Medicine in Paris and in March of the year 1844 they dispatched a commission to Lyons in order to observe and report to the Academy the works of this Reybard of Lyons. In July of that year the commission Messrs Blandin Bevard and Jobert de Lambelle (27) made their report. M Reybard lacking suitable clinical material had demonstrated his technique on dogs. In all 7 dogs were used in the demonstration. The results of this experiment were not good. Post mortem examinations revealed that adequate healing had not taken place between the ends of the anastomosed intestines. Some specimens had not healed at all and in others large fistulous openings were apparent. So, the commission concluded since the procedure was so unsuccessful in experimental animals was there any reason to believe that it would be more successful in man? The Academy thought not and so the one stage end to-end anastomosis of the colon as a method of treatment of carcinoma of the bowel was rejected by the Royal Academy of Medicine in Paris.

The history of colon surgery might have been entirely different had Reybard been acquainted with the work of one of his contemporaries that of Antoine Lembert.

M Lembert reported to the surgical section of the Royal Academy of Medicine in Paris his experimental work on dogs in which he had devised a method of suture which allowed the intestinal wound edges to heal rapidly and with excellent approximation. Altogether he had operated upon 5 dogs. All 5 dogs lived. He further observed that the operative procedure in most of the dogs scarcely interrupted their normal habits of eating and elimination. This report was made January 26, 1826. This method of suture is the basis of our modern technique in intestinal surgery. We speak of it as the Lembert suture.

Since this early report on the works of M Reybard to the French Royal Academy of Medicine surgery of the colon has passed through many painful phases. Although colostomy was known and had been performed by Pillare (10) in 1776 and successfully by Duret (10) in 1793 surgical resection of the diseased colon had not been reported. In fact during this period the only relief offered patients suffering from cancer of the distal colon, according to Thomas Copeland was the cauterization of the very painful hemorrhoids which developed as a consequence of the obstructed circulation in the parts. Copeland described the late stage of the disease very accurately. He states 'introduction of the finger into the rectum will be opposed by a hard ring of cartilagenous feel composed of the diseased inner ring of the intestine.' He also observed that despite vigorous treatment of the piles the true nature of the disease went unrecognized. According to Dinnick, whose excellent and very thorough work, 'The Origin and Evolution of Colostomy,' was published in 1934 it was not until the middle of the 19th century that colostomy became widely used.

From the general surgery service Temple University Hospital, and from the surgical service of Dr. W. Wayne Babcock, Temple University Hospital.

Abridgement of thesis submitted in March, 1948, by Dr. Cooke as required for the degree of M.S. in Surgery.

Dunnick states that Amussat (10) one of the foremost French surgeons of that time rescued (colostomy) from the realm of the occasional and heroic and advanced it to its proper place in surgery. In 1839 Amussat analyzed all the reported colostomies, of which there had been a total of 29 cases. From this critical survey and his own research into the anatomy of the colon he published his concept of when and how colostomy should be performed. This teaching fell on fallow ground, and the palliative colostomy became the accepted method of treatment of carcinoma of the colon.

In the year 1882 Bryant described a procedure in which resection was done after exteriorization of a portion of the colon and 10 years later Bloch of Copenhagen utilized the same principle. In 1895 Paul of Liverpool reported to the British medical profession his historic series of 7 cases of exteriorization and resection of the colon. In the author's own words this series represents the education of a surgeon. Although the end results in these cases were not good the careful analysis given each case and the application to the next operation of that which had been learned from the preceding one led Paul to the development of the operative procedure which today bears his name. This procedure received even more widespread acclaim after the publication of the excellent work of Mikulicz in 1903. Because of this work and the way it was presented to the medical profession this form of surgical treatment became known as the Mikulicz or the Mikulicz-Paul operation. The reason for this acclaim and almost universal acceptance of this procedure is obvious. At last some method of treating carcinoma of the colon had been devised which gave reasonable promise of curing the cancer without killing the patient. That dread scourge peritonitis, which attended all open intra-abdominal surgery had been relegated to a minor role. Mortality had been reduced from an almost prohibitive level to a relatively benign 15 to 20 per cent by this method.

Surgery of the rectum and rectosigmoid had also become important strides. In the year 1885 just a few years after the first published papers on exteriorization and resection of the colon Kraske (23) presented to the Fourteenth Con-

gress of German Surgeons an operative procedure which bears his name the Kraske perineal resection of carcinoma of the rectum. This method had many disadvantages, the most disturbing of which was the high percentage of recurrence of the tumor. Kraske himself realized this and in 1906 he reported a series of 10 cases in which the original technique had been modified to include an abdominal procedure which mobilized the rectosigmoid and rectum prior to removal through the perineum. Miles went a step further and brought the colostomy out on the abdominal wall. There it was to remain until Babcock (2) in 1932 proposed that the colostomy be returned to the perineum whence it came. In addition to perineal colostomy Babcock has long been a proponent of radical extirpation of carcinoma of the colon with preservation of functioning anal sphincters. Recent publications (3-4) on this subject outline his technique in detail. A type of sphincter saving operation had been reported as early as 1923 by Lockhart Mummery (16) who also called attention to the unnecessary sacrifice of the anal sphincters in many cases of carcinoma of the rectum and rectosigmoid.

At the turn of the century we see that medicine had advanced to the stage in which the objective was an attempt by radical excision of the tumor and the adjacent tissues to rid the patient of his cancer. Great strides had been made in surgery. This was a far cry from the hemorrhoidectomies of Copeland's time or the palliative colostomies of the 19th century. In spite of the excellent results reported by the advocates of these procedures, many surgeons still maintained an interest in an operation which would immediately re-establish continuity of the bowel following resection and thus eliminate the prolonged hospitalization and numerous surgical procedures necessitated by exteriorization of the bowel. As the anatomy and physiology of the intestinal tract became better understood, pioneering surgeons sought some method of colon anastomosis which would eliminate the troublesome Mikulicz and yet would not compromise the safety obtained by that procedure. Notable among these was the Johns Hopkins group the members of which, led by Halsted, became very active in experi-

mental work on intestinal anastomosis. In 1910, Halsted published his paper on the bulk head method of aseptic intestinal anastomosis. This was a very earnest effort to eliminate contamination at operation. In Halsted's own words, 'for the large intestine the circular suture or end-to-end anastomosis would if equally safe, be conceded to be the ideal method. Another method proposed by this group utilizing the basting stitch principle was published in the Johns Hopkins Hospital bulletin of 1908 by Parker and Kerr. The major obstacle to overcome in this suture and one which frequently occurred in experimental animals was the tendency for the formation of a diaphragm at the site of resection. All in all, these were important contributions and despite the disadvantages of each method something was learned with each painstaking step.

In 1917, in a very excellent work, Lockhart Mummery (17) described the technique which he utilized in open end-to-end anastomoses of the colon. By carefully packing off the peritoneal cavity at the time of operation and by careful attention to preoperative and post-operative care he believed that this procedure could be accomplished with reasonable success. The technique described in that treatise has scarcely been improved upon today.

In the years to follow end-to-end anastomosis of the colon was not widely used. Instead the Mikulicz exteriorization principle for carcinoma of the colon was utilized by most clinics. For cancer of the rectosigmoid and rectum, in which exteriorization was impossible, the abdominoperineal resection of Miles became the accepted treatment.

In 1939 a very important contribution to colon surgery was made. Garlock and Seeley published their report on the effect of oral sulfanilamide on intestinal bacteria. Since that report new and less toxic sulfanilamide products have been developed, and bacterial flora in the colon can be reduced to a minimum (26). At long last the proponents of one stage end-to-end anastomosis had added to their armamentarium the last necessary link. Peritonitis from contamination at operation had finally been successfully controlled.

Progress in colon surgery had been slow but steady. First began the development of the

technique of intestinal surgery the corner stone of which was the development of the Lembert suture. Next, perhaps was the gradual understanding by the medical profession of the anatomy and physiology of the gastrointestinal tract and particularly the absolute necessity for decompressive measures in cases of obstruction. This knowledge coupled with the evolution of the blood bank and the development of modern anesthetic methods and finally the elimination of gross contamination at operation as a major factor has brought us to the excellent method of treating carcinoma of the colon, first described by Reybard of Lyons 115 years ago.

TREATMENT IN 79 CASES

This paper is a survey of all end-to-end one stage anastomoses of the colon performed in the Temple University Hospital during the years 1945, 1946 and 1947. No ileocelectomies or perineal resections are included in this series.

There is no attempt in this paper to deal with the rate of cure in patients afflicted with carcinoma of the colon but rather to ~~examine~~ these cases from the standpoint of operative mortality, morbidity directly or indirectly contributed to by the operation and finally the end results of the operative procedures. Altogether there have been 79 cases in which resection of the colon with one stage end-to-end anastomosis was done. The majority of the lesions for which resection was done were malignant. A few, 14 in number, were benign. Four of the patients, for reasons to be explained later, were reoperated upon and resection again carried out at the same site.

There were 6 deaths from all causes which is a mortality rate of 7.5 per cent (Table I).

TABLE I.—DEATH IN 6 CASES

Cause of death	Case No.	Anteop.	Post operation
Coronary occlusion	8	75	15 hours
	64	75	15 days
Coronary occlusion and cerebral embolus from mural thrombus	4	75	9 days
Peritonitis	73	75	15 days
Small bowel obstruction	59	75	4 days
Sepsis (wound infection pyelonephritis-B. proteus aerob. septicemia-B. proteus)	27	75	21 days

If the 2 cases of coronary occlusion and the 1 of cerebral embolus are excluded the corrected mortality for 83 resections in 79 patients is 3.7 per cent.

Morbidity includes all complications directly or indirectly resulting from the operative procedure in the entire postoperative period. These cases will be discussed in more detail later.

Preoperative preparation. The preparation of these patients for surgery followed the same general pattern: complete mechanical cleansing of the bowel by purgatives and enemas followed by oral sulfasuxidine or sulfathiazidine, occasionally oral streptomycin and a low residue diet. Blood chemistry and hemoglobin levels were corrected in this preoperative period when necessary. In a few of these patients obstruction was present when they were admitted to the hospital and decompression was accomplished by either the Miller Abbott tube and 100 per cent oxygen inhalations or some form of colostomy. The method of decompression utilized depended largely upon the degree of obstruction and its duration.

Technique. The surgical technique falls into two general classifications: the open method of anastomosis and the closed or aseptic method in which a Furness clamp or a modification of it was used.

In the open technique the operative field was protected from gross contamination by rubber-shod Scudder clamps placed a comfortable distance from the severed ends of the bowel and complete isolation of the area with abdominal packs. In the majority of cases two rows of inverting sutures were used although in a few cases, only one row of interrupted silk completed the anastomosis. Gloves were changed and clean instruments used after completion of this stage of the procedure. Twenty-eight anastomoses were performed in this manner. One of the patients had a proximal vent in the form of a cecostomy established at the time of operation. Four patients had a functioning colostomy previously established because of obstruction when they came to the operating room.

The closed or aseptic technique made use of the Furness clamp and pin or a modification

of it. One method (3-14) of applying this clamp is to bring both segments of the bowel together at the site of proposed resection. The clamp is applied so that it includes both proximal and distal bowel with a loop above. The loop of bowel above the Furness clamp which includes the diseased portion is cut away below a Payr or another type of crushing clamp. When the Furness clamp is removed the pin holds both proximal and distal segments of bowel. After the anastomosis the pin is removed and the lumen of the bowel re-established by the operator's fingers. The other method of aseptic anastomosis utilizes two Furness clamps and two pins. The bowel is resected between the two clamps. When the suturing is to begin the two pins are approximated and the sutures placed. In general two rows of sutures were used. Fifty-five closed anastomoses were performed in this series. In these 55 procedures there were 33 with proximal vents, either appendicostomy, cecostomy or colostomy established at the time of operation. Four patients came to operation with some form of functioning colostomy which had been established previously because of obstruction.

Complications. Postoperative complications were many and varied. Those resulting in death have been listed. The case reports of the patients who died and of those contributing to the morbidity rate will be discussed in the following paragraphs.

CASE REPORTS

There were 3 cases of peritonitis. In 1 of these localization occurred and drainage was successful.

CASE 83. S. R., aged 53 years, male. The diagnosis was carcinoma of the descending colon, with no metastases. Aseptic anastomosis without proximal vent was done. His progress was good, bowels began to move on the 3rd day after operation. On the 10th day a localized intra-abdominal abscess was drained through the outer edge of the wound. The patient was never very ill, but because of the localized peritonitis, was not discharged until the 24th postoperative day. The operative result was good.

The other 2 cases of peritonitis detailed in the following paragraphs are also listed in our mortality column.

CASE 73. D. R., aged 63 years, female. This patient had carcinoma of the descending colon. The

operation was resection and aseptic anastomosis with complementary appendicostomy. She was reoperated upon on the 8th postoperative day because of mechanical ileus and at this time an ileostomy was done. Eleven days after the first operation the patient was operated upon again and drainage established for the peritonitis. She died of peritonitis on the 18th postoperative day. No autopsy was obtained. Although it was believed because of the findings at later operation that peritonitis was not a result of a leak at the colon anastomosis, this patient was signed out as death due to peritonitis following colon resection because of the lack of autopsy proof.

CASE 64. M. A. aged 67 years female. The diagnosis in this case was colloid carcinoma of the transverse colon. Operation was resection and closed end-to-end aseptic anastomosis without proximal vent. Progress was apparently satisfactory until the third postoperative day when the temperature began to spike to 102. On the 6th postoperative day by x-ray examination the distention was interpreted as obstruction at the hepatic flexure. The patient was operated upon and cecostomy done. At operation turbid intraperitoneal fluid was found, positive culture, nonhemolytic *Staphylococcus albus* also dilated small bowel. Cecum and terminal ileum were not distended. The patient responded slowly. Following cecostomy temperature continued to spike up to 102 daily. The patient was gotten out of bed and apparently was recovering with bowels moving well when she suddenly went into shock and died 6 days after cecostomy and 12 days following resection. Autopsy revealed coronary thrombosis as the immediate cause of death. She also had minimal peritonitis from a small leak at the anastomosis.

In 6 cases postoperative small bowel obstruction occurred.

In 2 of these cases there was evidence of obstruction in the immediate postoperative period which was successfully treated with the Miller Abbott tube.

CASE 70. A. S. aged 48 years female. Diagnosis was carcinoma of the rectosigmoid. Operation was resection and open end-to-end anastomosis without proximal vent. The patient responded well until the 4th postoperative day when distention became evident and the next day x-ray examination revealed small bowel obstruction. Miller Abbott tube was passed and obstruction was relieved. The patient was discharged on the 15th postoperative day.

CASE 67. D. S. aged 48 years male. This case will be discussed in more detail under late obstructions. It is included here because the Miller Abbott tube was used until the 22nd postoperative day. Following the removal of the tube the patient was discharged in apparently good condition.

In 1 case a cecostomy was done 3 days after operation.

CASE 1. M. S., aged 63 years, male. The diagnosis was carcinoma of the sigmoid. The lesion was resected and a closed type anastomosis without a proximal vent was performed. The patient showed evidence of distention early in the postoperative period. This was unrelieved by the Miller Abbott tube and on the 3rd day a cecostomy was done as a decompressive measure. Following this the patient's condition improved and except for a febrile response the postoperative course was smooth.

The following cases were readmissions of patients who had developed ileus a considerable time after resection. This type of complication can and does follow any type of abdominal surgery but for the sake of completeness they are included here.

CASE 8. C. H., aged 56 years female. Diverticulitis of the sigmoid was diagnosed. Resection and aseptic end-to-end anastomosis with complementary cecostomy were performed. The patient apparently had an uneventful postoperative course was on liquids on the second day and soft diet on the sixth day. She was discharged on the 28th postoperative day. No reason is given on the chart for this prolonged stay. Presumably the patient wished to remain until the cecostomy was completely healed. Nine months later she was readmitted with chronic obstruction. Operation revealed many dense adhesions about the old scars (hysterectomy and sigmoidectomy). Separation of these adhesions apparently relieved the patient's symptoms. She has been well for 18 months.

CASE 67. D. S. aged 48 years, male. Volvulus recurrent with stenosis at the base of the volvulus was the diagnosis in this case. After adequate preparation the redundant sigmoid was resected and an open end-to-end anastomosis done without proximal vent. A Miller Abbott tube had been passed preoperatively. The course in the hospital was not uneventful. Each attempt to close the Miller Abbott resulted in abdominal distention. Although the patient was taking food well the Miller Abbott tube was not removed until the 22nd day. The impression was that the small bowel had been obstructed by adhesions. After being free of symptoms this patient was readmitted 18 months later with obvious mechanical small bowel obstruction. Operation revealed a narrow adhesion obstructing the lower jejunum. Smooth postoperative course followed lysis of this adhesive band. There has been no recurrence of symptoms.

The other 2 cases of intestinal obstruction are listed in our mortality column.

CASE 50. J. H. aged 73 years male. This patient had carcinoma of the transverse colon. After suitable preparation resection of the tumor and an aseptic end-to-end anastomosis was done without a proximal vent. The patient responded well after operation and was making an apparently normal re-

covery until the 3rd postoperative night when he complained of abdominal pain and began to vomit. This condition went unrecognized until the following morning at which time the patient was quite ill and in a state of vascular collapse. Under local anesthesia the abdomen was explored and a high intestinal obstruction was found. The walls of the distended jejunum were dusky blue in color. The obstruction was relieved but the patient failed to respond and died a few hours later. Autopsy was obtained and corroborated the clinical findings.

CASE 73. D. R., aged 63 years, female. This case has already been described under peritonitis which was the cause of death although a small bowel obstruction was found at second operation. Autopsy was not obtained and complete analysis is, therefore impossible.

Failure of the anastomosis to function occurred in 4 cases. These are described in detail below.

CASE 63. A. S., aged 43 years, male. Diagnosis was ulcerative colitis. The distal two-thirds of the transverse colon, descending colon and the proximal two-thirds of the sigmoid were resected. Anastomosis between proximal transverse colon and distal sigmoid was the open type. A functioning ileostomy had previously been established. The postoperative course was completely uneventful. Sixteen months later the patient was readmitted because of obstruction. Operation at this time revealed that extreme tension between the transverse colon and sigmoid had elongated and narrowed the lumen to such an extent that it was partially obstructed. A resection and closed end-to-end anastomosis was done with complementary appendicostomy. Postoperative course was uneventful and patient was discharged on the 30th day.

CASE 10. M. P., aged 38 years, female. Carcinoma of the sigmoid was the diagnosis. The sigmoid was resected and an aseptic end-to-end anastomosis performed with complementary cecostomy. The postoperative course was good for the first few days. The cecostomy was allowed to close. On the 17th day it was apparent that there was obstruction at the site of the anastomosis and a colostomy was done. Four weeks after the original operation another resection was carried out and an aseptic closure made. The excised specimen showed a complete diaphragm had formed at the site of the original anastomosis. The course following this procedure was uneventful and the patient was discharged on the 13th day.

CASE 29. M. P., aged 63 years, female. Diagnosis was redundant sigmoid—obstipation severe. After adequate preparation the sigmoid was resected and an aseptic end-to-end anastomosis performed with complementary cecostomy. The patient responded well for the first few days, but it soon became apparent that something was wrong at the site of anastomosis. Obstipation persisted despite efforts to stimulate movement via the cecostomy. The tem-

perature and pulse were normal, however and the patient was not ill. On the seventh day she was re-operated upon. A small area of necrosis was found at the site of resection. A rectal tube was passed from below up through the anastomosis and a drain placed retroperitoneally down to the suture line. Following this maneuver the patient made a normal recovery.

CASE 56. H. K., aged 60 years, male. This patient had had several operations for peptic ulcer elsewhere. On admission there was evidence of gastrocolic fistula. At operation, an anterior and a posterior gastroenterostomy were found. The loop encircled and compressed the colon. A marginal ulcer with colonic fistula and a chronically perforating duodenal ulcer were present. A partial gastrectomy with resection of the involved jejunum was completed. The obstructed colon was then resected and an aseptic end-to-end anastomosis was performed without a proximal vent. The patient responded well but on the 7th day it was evident clinically and by x-ray examination that obstruction existed at the site of colon anastomosis. A cecostomy was done. On the 27th day a plastic procedure on the colon established an adequate lumen. The patient was discharged with a good operative result.

There were 3 cases of coronary occlusion. Two of these are of particular interest because they occurred just a few hours after completion of operation.

CASE 81. F. W., aged 70 years, male. Diagnosis was carcinoma of the sigmoid. In addition the patient had hypertension (diastolic blood pressure 186/95) and gave a history of having had a coronary occlusion 3 years before admission. After suitable preoperative preparation the patient was operated upon and an aseptic end-to-end anastomosis with a complementary cecostomy was performed. During the operation which was done under spinal anesthesia, the blood pressure dropped to 75/50 where it remained for 30 minutes. It gradually rose until at the end of an hour and 15 minutes it had risen to 115/70. The patient was returned to his room in apparently good condition. Two hours later he suffered a heart attack and died 3 hours after operation. Autopsy revealed the suspected coronary occlusion.

CASE 42. F. H., aged 57 years, male. Diagnosis was carcinoma of the sigmoid partially obstructing. The obstruction was relieved by the Miller Abbott tube enemas and oxygen inhalations. After suitable preparation the patient was operated upon and resection of the sigmoid in the open manner without a proximal vent was performed. During the operative procedure the blood pressure remained fairly constant. Before anesthesia, continuous spinal, the blood pressure was 90/70. Twenty minutes after the spinal was given, the pressure dropped to 70/50 where it remained for 30 minutes. Toward the end of the procedure it again dropped to 70/50 where it

remained for 15 minutes. With stimulants it rose to 100/70. One hour and 30 minutes after operation the patient experienced severe subabdominal pain. Electrocardiogram revealed a posterior infarction. The cardiac disease responded to therapy and the anastomosis was functioning well, soft diet, and bowels moving until the evening of the 8th day at which time the patient had a cerebral accident. Twenty-four hours later there was extension of this process and the patient died. Autopsy revealed a cerebral embolus originating probably from the mural thrombus as the cause of death. The myocardial infarction was demonstrated.

These cases of coronary occlusion which occurred within a few hours after operation can not be dismissed with a wave of the hand and classified as unavoidable catastrophes. In both of these patients a cardiac history was obtained. In the first case a definite history of infarction was given and in the second a history of anginal pain of such magnitude that the patient had seen a cardiologist was discovered after operation. Both patients were cardiac problems before they developed cancer. The type of anesthesia to be used in such cases is always a problem. Spinal was used in both cases. The wisdom of this choice is open to question. The important point is to see that there is no drop in blood pressure for an appreciable period during the operative procedure. In any event in a certain percentage of these cases death will result from cardiac disease.

The third case of coronary occlusion has already been reported under peritonitis. That is Case 64. The occlusion was brought on in all probability by the patient's stormy postoperative course.

Several other cases presented complications which should be considered.

The following case is listed in our mortality column.

CASE 27 E. R. aged 68 years female. The diagnosis was carcinoma of the sigmoid with complete obstruction on admission. From the history the duration of the obstruction was 3 weeks. Cecostomy was performed as a decompressive measure. The patient was quite ill and 2 weeks were spent in preparation for definitive surgery. The sigmoid was resected and open anastomosis done. Preparation of the bowel was definitely not good. The cecostomy was inadequate. The immediate postoperative period was fairly good, despite the fact that there was a temperature elevation up to 104. On the 9th day a

urine culture was positive and the urine was loaded with pus cells. During this period the patient was having on the average of three stools per day. Careful examination of the operative site revealed no evidence of intra abdominal infection. The wound was superficially infected. Temperature began to rise on the 10th day. The organisms (*Bacillus pyocyaneus*) in the urine and wound failed to respond to antibiotics. This situation continued and the patient died on the 24th day. Prior to death a positive blood culture of *Bacillus pyocyaneus* was obtained. This death was attributed to sepsis. No autopsy was obtained.

Urinary fistula occurred in 1 case.

CASE 37 F. M. aged 51 years female. Diagnosis was sigmoid carcinoma. The patient was adequately prepared and resection with an aseptic anastomosis with complementary cecostomy was performed. During the operative procedure the left ureter was divided and anastomosed. In the postoperative period the patient developed urinary fistula and later it became necessary to do a nephrectomy. She recovered and has remained well since.

In the next case the patient developed a fecal fistula.

CASE 12 J. R. aged 59 years female. This patient had diverticulitis of the sigmoid. She was admitted with two colostomies, one at the sigmoid and the other at the ascending colon. In addition this patient had fistulous tracts and abdominal wall abscesses. After incision and drainage of the abscesses and adequate preparation of the bowel a closed type of resection was done at which time the sigmoid colostomy was eliminated. The postoperative course was not eventful and after closure of the colostomy the patient was discharged. Two months later she was readmitted. A fecal fistula had developed at the site of the sigmoid anastomosis. After adequate drainage of this tract and preparation of the bowel the involved area was resected and an open anastomosis done with complementary appendicostomy. Recovery was uneventful.

The following case is presented because two resections were done at the same site.

CASE 70 J. S. aged 59 years male. Diagnosis was carcinoma of the sigmoid. After adequate preparation the sigmoid was resected and anastomosed openly without a proximal vent. Postoperative course was uneventful. Microscopic examination revealed that tumor existed in the cut edge of some of the tissue removed and so on the 12th day the patient was reoperated upon and resection again done at the same site. Open anastomosis without proximal vent was performed. Recovery was otherwise uneventful. A superficial abscess was drained on the 7th day. Patient was discharged on the 14th day.

There were no cases of pulmonary embolism in this group but 2 patients developed signs and symptoms of phlebothrombosis. Neither of these cases was serious and both responded well to anticoagulant therapy.

CASE 5: A. C., aged 71 years, female. Diagnosis was carcinoma of the transverse colon which, on admission, was causing obstruction. The obstruction was relieved by use of the Miller Abbott tube and enemas. The patient was operated upon and aseptic anastomosis accomplished without proximal vent. At the time of operation the Miller Abbott tube was at the site of the lesion. Postoperative course was uneventful except for signs and symptoms of phlebothrombosis which became apparent on the 7th day. This was successfully treated with anticoagulants and the patient was discharged on the 15th day.

CASE 43: B. W., aged 64 years, male. The diagnosis was carcinoma of the rectosigmoid. Resection and open end to-end anastomosis of the upper sigmoid to the rectum without proximal vent were performed. Rectal tube was passed through the anastomosis from below at operation. The postoperative course was marred by atelectasis and on the 12th day diarrhea became a troublesome complaint. The patient had an indwelling catheter postoperatively because of retention and attempts to remove this were fruitless and he was discharged with catheter in place. Also while in the hospital he showed some tenderness in the left calf which was interpreted as phlebothrombosis. This responded to heparin and dicumarol. Three months later these complaints had disappeared.

In the following case the patient developed a wound infection of such magnitude that his hospital stay was prolonged until the 29th postoperative day.

CASE 16: S. C., aged 73 years, male. After suitable preparation a closed resection and anastomosis with complementary appendicostomy were done. The patient responded well except for a temperature elevation to 103.6 on the second day. On the 4th day it was 103, despite this the patient was on surgical liquids and his bowels had moved twice. He continued to improve and his temperature elevation declined by lysis. On the 20th day a large abscess was found in the lower edge of the incision and drained. He was discharged on the 29th day.

The inclusion of this complication under wound infection rather than under localized peritonitis is open to question. The fact that ileus was not present in an unusual degree has persuaded us to classify this case as one of wound infection.

CARCINOMA OF THE RECTOSIGMOID

Resection of lesions in the rectosigmoid should rightly be considered as a separate group. This method of anterior resection and end to-end anastomosis was used in 8 cases. Six of these 8 procedures were performed in the last year of this 3 year report. The technique as advocated in recent years by Dixon was modified somewhat. In none of these cases was the pelvic peritoneum approximated over or about the anastomosis and in none was a presacral drain utilized. The technique used varied only in the type of anastomosis and whether or not use was made of a proximal vent as a complementary procedure.

In 5 cases resection and anastomosis were carried out in the aseptic manner with complementary appendicostomy or cecostomy. In the 3 remaining cases resection and anastomosis were by the open technique without a proximal vent. In all 3 of these cases a rectal tube was passed from below up through the anastomosis at the time of operation. This maneuver which has been described by Waugh and Custer and prior to them by Stone and McLanahan has also been very useful in our hands.

Complications in this group of 8 cases have been remarkably few. No evidence of peritonitis developed and fecal fistulas were notably absent. One patient Case 43 with carcinoma of the rectosigmoid who had an open type anastomosis without proximal vent with rectal tube through anastomosis, already described under phlebothrombosis, developed a troublesome diarrhea on the 12th postoperative day. In addition he had urinary retention and at one time in his early postoperative period he developed atelectasis. With treatment these complaints disappeared.

The only other complication was in Case 79 with carcinoma of the rectosigmoid. Operation was open anastomosis without proximal vent with a rectal tube through the anastomosis. This patient developed postoperative ileus which responded promptly to intubation. This case is described under intestinal obstruction.

These postoperative complications were not of a serious or lasting nature and the operative results have been good.

SUMMARY AND CONCLUSIONS

In summarizing this report our attention is first directed to the 6 patients who died as a result of the operative procedure. There were 3 cases of coronary occlusion. Two of the 3 cases of occlusion occurred within a few hours after operation. Both of these patients came to operation with definite cardiac disease. Myocardial disease is not an uncommon finding in patients in this age group and every effort should be made to evaluate their cardiac status before operation. In every situation in which cardiac disease is present it is imperative that all precautions be taken to prevent embarrassment of the coronary circulation. A drop in blood pressure from whatever cause anesthesia or prolonged surgery should require the urgent attention of all concerned. Only in this way will this type of mortality be reduced. In all probability the third case of coronary occlusion occurred as a result of the undue strain put upon the heart by the stormy postoperative course. This must of course be considered a preventable death.

In the case of the 1 patient who died of small bowel obstruction we were guilty of an error in management. This patient died because the obstruction existed unrecognized for 12 hours.

One patient died of sepsis. This patient had remained at home with an obstruction for 3 weeks before admission. It is not easy to classify this as a preventable death. If there was an error it was probably due to the fact that a permanent type of colostomy was not done for decompression and perhaps a much longer time should have been allowed to lapse before definitive surgery was attempted.

The 1 case of peritonitis must of course be considered a technical failure.

Review of the statistics brings to light some very interesting facts. In comparing the two general types of anastomosis it is noteworthy that peritonitis was not evident in any of the

5 cases of open end to end anastomoses. Three cases of peritonitis occurred in the group of aseptic or closed anastomoses. Of the 4 cases in which the anastomosis failed to function 3 were in the closed and 1 in the open group. Open anastomosis as a routine procedure has been reported by some authors (1

18 19 20 31). In our small series conclusions are dangerous but speculations are certainly in order. Since these cases represent the surgical techniques of a group rather than an individual the speculations become even more justifiable. One explanation of our results is that all things being equal it will probably be conceded by most surgeons that a more exact suture can be placed in an open type of anastomosis than in a closed type.

The question of establishing a proximal vent or safety valve at the time of operation has always been a controversial one. As so often is the case in surgery time modifies some of our most pronounced convictions. In 1931 in reviewing all of the colon cases in Peter Bent Brigham Hospital Cheever wrote "no surgeon of experience would advise as a routine primary resection with suture anastomosis in the distal colon without making a proximal safety valve. In the same article the author expressed doubt of the efficacy of a proximal vent in the right sided colon resections. Fourteen years later Wangenstein states (complemental) colostomy is not necessary and Vaughn and Custer. There is little question in our minds that colostomy is an unnecessary addition to resection performed for lesions of the sigmoid or above. However our feeling in regard to its use in lower lying lesions is not so definite. In that same year in their report on 173 cases of carcinoma of the colon Collier and Vaughn concluded that a complementary cecostomy is a wise safeguard in primary resection of the colon.

In our series complemental vents were established in 52 of the 83 resections. If we eliminate the postoperative complications which were remote from the operative site such as coronary occlusion and phlebotrombosis and carefully analyze the remaining 13 complicated cases we find the following facts. There were 6 cases in which a proximal vent as a complemental procedure was not established. In only 3 of these would a proximal vent have conceivably been of any benefit. In

of these 3 cases cecostomy was done with good result. In the third case the localized infection was at no time severe enough to warrant intervention. In the 7 cases in which

a proximal vent was established as a complementary procedure there were 3 in which the proximal vent was of obvious benefit

In the light of these figures the following conclusions seem justifiable

In low lesions a tube through the anastomosis seems to eliminate the necessity of a proximal vent

In uncomplicated resections in which adequate lumen and undoubted blood supply to the parts are assured a proximal vent is an unnecessary maneuver

In cases in which trouble develops at the suture line such as obstruction or leakage a proximal vent is a valuable adjunct but it seems reasonable to assume that such a vent could be established as the necessity arose rather than as a routine procedure

PSEUDOCYSTS OF THE PANCREAS

Report of 31 Cases

KARL A. MEYER M.D. F.A.C.S. Chicago Illinois ALFRED I. SHERIDAN M.D.
Seattle Washington and RICHARD F. MURPHY M.D., Chicago, Illinois

EVER since 1761 when Morgagni first described the multiple cysts of the pancreas mesentery and omentum which he found in a cadaver the etiology diagnosis and treatment of pancreatic cysts has continued to be a challenging problem. Even such a basic prerequisite to the solution of this fascinating problem as an adequate pathological classification of pancreatic cysts has been impeded by difficulties which have not yet been overcome. The confusion in pathological terminology has resulted from disagreement regarding the origin and pathogenesis of the cysts.

Of all the pancreatic cysts the so called pseudocysts have been the most difficult to define properly. The term pseudocyst has usually been given to encysted fluid collections in the peripancreatic tissues of the lesser omental sac. The absence of an epithelial lining of the fibrous connective tissue wall of the pseudocyst has been used to differentiate it from true pancreatic cysts such as cystadenomas retention and proliferation cysts. But this differential criterion is not infallible and may lead to an erroneous pathological diagnosis. For example a large retention cyst may be indistinguishable from a pseudocyst if its epithelial lining should undergo pressure atrophy. Further it is possible that some pancreatic pseudocysts possess an epithelial lining which subsequently is destroyed by activated pancreatic enzymes or atrophies from pressure. Such possibilities as these make an accurate pathological diagnosis based upon the presence of an epithelial lining impossible in all pancreatic cysts.

Another intriguing aspect of pancreatic cysts is the observation that the pancreas is the only parenchymatous organ in the body

which reacts to trauma or inflammation by self destruction and the formation of a pseudocyst. Several reasons for this immediately suggest themselves. First its anatomical position astride the vertebral column makes it particularly vulnerable to blunt trauma. Second the pancreas responds to trauma or inflammation by pouring out large amounts of fluid which may or may not contain activated enzymes. The abundant blood supply of the pancreas and its ability to secrete approximately 800 cubic centimeters of pancreatic juice per day in the average adult seem to account for its profuse secretion when injured or inflamed. The presence of this irritating pancreatic secretion in the lesser omental sac appears to provoke a chemical peritonitis with a further outpouring of inflammatory fluid which eventually becomes encysted.

The most compelling phase of the problem of pancreatic pseudocysts is the surgical treatment. At present sharp differences of opinion exist regarding the employment of complete excision marsupialization or internal drainage of these cysts. The multiplicity of opinions as to the most desirable surgical procedure prompted us to review our experience with pseudocysts in an effort to evaluate the results of the procedures employed. From 1930 to 1947 inclusive 31 pseudocysts were operated upon at the Cook County Hospital and on the private service of one of us (K.A.M.). Pseudocysts which have been previously reported in the literature are found in Table I.

ETIOLOGICAL FACTORS

A division of our 31 cases according to sex showed an equal distribution between male and female. 15 cases (48.4%) occurred in male patients while 16 cases (51.6%) occurred in female patients. This distribution differs from the experience of Rabinovitch and Pine-

a proximal vent was established as a complementary procedure there were 3 in which the proximal vent was of obvious benefit

In the light of these figures the following conclusions seem justifiable

In low lesions a tube through the anastomosis seems to eliminate the necessity of a proximal vent

In uncomplicated resections in which adequate lumen and undoubted blood supply to the parts are assured a proximal vent is an unnecessary maneuver

In cases in which trouble develops at the suture line such as obstruction or leakage a proximal vent is a valuable adjunct but it seems reasonable to assume that such a vent could be established as the necessity arose rather than as a routine procedure

PSEUDOCYSTS OF THE PANCREAS

Report of 31 Cases

KARL A. MEYER, M.D., F.A.C.S., Chicago Illinois ALFRED I. SHERIDAN, M.D.,
Seattle Washington and RICHARD F. MURPHY, M.D. Chicago, Illinois

EVER since 1761 when Morgagni first described the multiple cysts of the pancreas mesentery and omentum which he found in a cadaver the etiology diagnosis and treatment of pancreatic cysts has continued to be a challenging problem. Even such a basic prerequisite to the solution of this fascinating problem as an adequate pathological classification of pancreatic cysts has been impeded by difficulties which have not yet been overcome. The confusion in pathological terminology has resulted from disagreement regarding the origin and pathogenesis of the cysts.

Of all the pancreatic cysts the so called pseudocysts have been the most difficult to define properly. The term pseudocyst has usually been given to encysted fluid collections in the peripancreatic tissues of the lesser omental sac. The absence of an epithelial lining of the fibrous connective tissue wall of the pseudocyst has been used to differentiate it from true pancreatic cysts such as cystadenomas retention and proliferation cysts. But this differential criterion is not infallible and may lead to an erroneous pathological diagnosis. For example a large retention cyst may be indistinguishable from a pseudocyst if its epithelial lining should undergo pressure atrophy. Further it is possible that some pancreatic pseudocysts possess an epithelial lining which subsequently is destroyed by activated pancreatic enzymes or atrophies from pressure. Such possibilities as these make an accurate pathological diagnosis based upon the presence of an epithelial lining impossible in all pancreatic cysts.

Another intriguing aspect of pancreatic cysts is the observation that the pancreas is the only parenchymatous organ in the body

which reacts to trauma or inflammation by self destruction and the formation of a pseudocyst. Several reasons for this immediately suggest themselves. First its anatomical position astride the vertebral column makes it particularly vulnerable to blunt trauma. Second the pancreas responds to trauma or inflammation by pouring out large amounts of fluid which may or may not contain activated enzymes. The abundant blood supply of the pancreas and its ability to secrete approximately 800 cubic centimeters of pancreatic juice per day in the average adult seem to account for its profuse secretion when injured or inflamed. The presence of this irritating pancreatic secretion in the lesser omental sac appears to provoke a chemical peritonitis with a further outpouring of inflammatory fluid which eventually becomes encysted.

The most compelling phase of the problem of pancreatic pseudocysts is the surgical treatment. At present sharp differences of opinion exist regarding the employment of complete excision marsupialization or internal drainage of these cysts. The multiplicity of opinions as to the most desirable surgical procedure prompted us to review our experience with pseudocysts in an effort to evaluate the results of the procedures employed. From 1930 to 1947 inclusive 31 pseudocysts were operated upon at the Cook County Hospital and on the private service of one of us (KAM). Pseudocysts which have been previously reported in the literature are found in Table I.

ETIOLOGICAL FACTORS

A division of our 31 cases according to sex showed an equal distribution between male and female. 15 cases (48.4%) occurred in male patients while 16 cases (51.6%) occurred in female patients. This distribution differs from the experience of Rabinovitch and Pines

From the Department of Surgery, Northwestern University Medical School, Cook County Hospital and the Cook County Graduate School of Medicine.

Chart Age distribution of 31 cases.

who found all of their 11 cases in female patients. This preponderance of female patients in their series may be explained by the fact that none of their patients suffered trauma, and the incidence of associated chronic cholecystitis and acute and chronic pancreatitis was high. These latter conditions are statistically more common in females.

The age distribution of the 31 cases is recorded in Chart 1. An analysis of the ages of the patients revealed a fairly even distribution between the ages of 20 and 60. The youngest patient was 14 years old and the oldest was 64 years old and the average age was 40.6 years. Telling and Dobson reported a pancreatic cyst in an 11 month old child. A congenital cyst of the pancreas without an epithelial lining was reported in a 5 month old infant by Eha.

A summary of the racial distribution revealed that 23 cases (74%) occurred in white patients while 8 cases (26%) occurred in negro patients. A survey of hospital admissions during these years showed that approximately the same proportion of white and colored patient admissions existed. Therefore no marked racial predilection was observed.

Blunt trauma to the pancreas, acute and chronic cholecystitis and acute and chronic pancreatitis are frequently associated with pseudocysts. Both clinical and experimental evidence is available which suggests that these factors are responsible for the production of pseudocysts. Lazarus experimentally produced a pseudocyst in a dog by crushing the

pancreas. A hematoma formed which later became an encapsulated cyst containing 100 cubic centimeters of milky fluid.

In our series, a history of trauma was elicited in 16 (51.6%) of the 31 cases. Koert obtained a history of trauma in 33 (28%) out of 117 cases. Judd (17) noted trauma in only 1 of his 44 cases. More recently Pinkham stated that trauma occurs in 20 per cent, or less, of cases. A possible explanation of the higher incidence of trauma in our series is the fact that our patients are drawn from an indigent population which is more prone to incur trauma. The time interval between the traumatic incident and the discovery of the pseudocyst averaged 5 months. The shortest time was 24 hours and the longest was 4 years. The trauma to the abdomen was severe in all cases and resulted from a variety of injuries such as kick in the abdomen, 4 automobile accident, 4 punch in abdomen, 5 fall on iron post, struck by baseball and not recorded each 1 case.

Cholecystitis and pancreatitis appeared to be etiological factors in 6 of our cases (16.4%). Cholelithiasis and chronic cholecystitis was found at surgery in 3 cases. In 1 case, acute cholecystitis was observed at surgery. A history suggestive of acute pancreatitis was obtained in 2 cases. The incidence of biliary and pancreatic disease was somewhat lower in our series than is reported by other authors. Adams and Nishijima reported cholelithiasis in 2 (40%) of their 5 cases. Pinkham reported

Fig. 1 Barium meal shows alteration of rugal pattern in pyloric region

Fig. 2 Anteroposterior roentgenogram shows the upward displacement of the pyloric region

6 cases (60%) out of 10 in which the pseudocyst was associated with pancreatitis and in 4 of these (40%) there was concurrent biliary tract disease. Judd (17) reported 17 (36%) out of 47 pancreatic cysts had biliary tract disease. Archibald (2) also noted the frequent association of biliary tract disease with bile pancreatitis and subsequent necrosis and pseudocyst formation. McWhorter reported 2 cases (33%) out of 6 in which the pseudocyst followed pancreatitis. From these data it is apparent that the etiological relationship of trauma, cholecystitis and pancreatitis to pseudocyst formation in our series coincides with the prevailing clinical impression on this point.

PATHOLOGY

The pathogenesis of pseudocysts as the discussion of their etiology has indicated is intimately related to trauma to the pancreas and to cholecystitis and pancreatitis. A consideration of the etiology of acute pancreatitis

and its relation to cholecystitis is not within the scope of this paper. For further information regarding this subject the reader is referred to the excellent papers of Opie, Archibald (2), Dragstedt, and Rich and Duff. Whatever the inciting agent may be the response of the pancreas to acinar damage is an escape and activation of trypsinogen and lipase with progressive focal necrosis and hemorrhage in the parenchyma of the gland. When this process of necrosis reaches the anterior surface of the gland it ruptures into the lesser omental sac where it produces a chemical peritonitis with a profuse inflammatory exudate from the adjacent serosal and peritoneal surfaces. If the foramen of Winslow is sealed off by this exudate the lesser omental sac is converted into a closed space within whose confines the exudate becomes encapsulated by the proliferation of fibrous connective tissue from the adjacent mesothelium lined surfaces during the reparative

Fig. 3. Oblique roentgenogram shows marked deformity of the posterior wall of the stomach and retrogastric radioopaque mass.

phase of the inflammatory process. The fibrous connective tissue which forms the cyst wall has numerous strands and dense adhesions to its parent surfaces, namely the structures which delimit the lesser omental sac. It is these adhesions which make complete excision of a large pseudocyst a difficult procedure. Carter and Slattery reported 2 cases in which the common duct was inadvertently opened during the excision of a pseudocyst. From the foregoing it is evident that the pathogenesis of pseudocysts is incumbent upon the response of the pancreas to injury by enzymatic autolysis and upon the location of the gland in a potentially closed space.

The position of the pseudocysts has been well described in previous papers. In our series the cyst presented itself through the gastrocolic omentum most frequently and through the gastrohepatic omentum less often. A retrogastric position of the cyst with the stomach pushed forward occurred with a fre-

quency equal to the gastrohepatic presentation. In one case the cyst presented itself through the gastrosplenic ligament, displacing the stomach anteriorly and to the right. In one instance the cyst presented in a retrogastric position causing the stomach to be tautly flattened over the cyst wall and producing pyloric obstruction. The excessive frequent vomiting which occurred in this patient plus a previous laparotomy scar on the upper abdomen led to the erroneous diagnosis of high intestinal obstruction.

The relation of the cyst to the various sectors of the anterior abdominal wall was as follows. In 2 cases the presence or absence of a mass was not recorded. In 3 of the remaining 29 cases (10.3%) no mass was palpated. In 12 (46%) of the 26 cases in which a mass was noted it was found in the left hypochondrium. The mass occupied the epigastrium next most frequently, being present there in 8 cases (31%). In no instance was the mass observed below the umbilicus. The mass appeared in the right hypochondrium in 1 case in the epigastrium and right hypochondrium in 2 cases in the epigastrium and left hypochondrium in 3 cases.

The amount of fluid contained in the cyst varied in the 16 cases in which it was measured. The smallest amount was 15 cubic centimeters and the largest 7,000 cubic centimeters. The average was 2,686 cubic centimeters. The color of the fluid was chocolate brown in 39 per cent, yellow or straw colored in 39 per cent, milky in 11 per cent, and hemorrhagic in 11 per cent. Pancreatic enzymes in the cyst fluid were tested for in 12 cases. In 9 of these (75%) enzymes were present and amylase, trypsin and lipase were found. Rabinovitch and Pines reported the presence of enzymes in 9 of their 11 cases. In the remaining 2 cases the tests were not performed.

X-RAY AND LABORATORY AIDS IN DIAGNOSIS

In the diagnosis of pseudocysts x-ray films proved far more useful in our hands than did laboratory tests. In the 8 cases in which scout films of the abdomen were taken a radioopaque mass was evident in 7. A barium meal was given in 14 cases and in 13 of these the

Fig 4. Abdomen opened exposing the stomach displaced anteriorly by the retrogastric cyst

stomach was displaced (Figs 1 to 3). In this regard it is interesting to note that Pinkham reported the use of gastric pneumograms to outline the pseudocyst. A barium enema was administered in 7 cases and the transverse colon was displaced in 6 of these.

Glycosuria was not detected in the routine urinalyses made in the 31 patients. The blood sugar level was determined in 6 cases and was found to be within normal limits.

A serum amylase determination was made in 8 cases. In 2 of these cases (25%) the amylase was elevated preoperatively to 124 and 96 units respectively. In both cases a ruptured cyst was found at operation. In 1 of these ruptured cysts, one in which the pseudocyst followed an acute pancreatitis, the serum amylase was elevated to 148 units on the fifteenth day after marsupialization. Pinkham noted an elevated preoperative serum amylase in 6 of his cases which dropped promptly after drainage in 4 cases. It is Pinkham's opinion that a sustained elevation of the serum amylase after acute pancreatitis is suggestive of the development of a pseudocyst.

SURGICAL TREATMENT

The first recorded attempt to treat a pancreatic cyst surgically was made by Le Dentu in 1862 (17). He punctured and drained the cyst but peritonitis developed subsequently and the patient died. Similarly, Lucke (17) in 1866 drained a pancreatic cyst and the patient died. Not until 1861 when Bozeman (17)

Fig 5. Cyst exposed by division of the gastrocolic omentum and dissected from the posterior surface of the stomach. Note the roughened area on the stomach with numerous vessels ligated where the cyst was adherent.

extirpated a pancreatic cyst was the first successful operation performed. Gussenbauer (17) a pupil of Billroth's in 1882 performed the first marsupialization of a cyst with success. Marsupialization was the only surgical procedure performed for pseudocysts until 1927 when Hahn anastomosed the cyst to the jejunum. In 1927 Walzel anastomosed the cyst to the gall bladder and ligated the cystic duct to prevent bile from entering the cyst. In 1931 Jurasz and Jedlicka each reported a case in which the pseudocyst had been anastomosed to the stomach. Judd, Matson and Mahorner (17) reported 47 cases in 1931. Seven of these cysts were completely excised, 33 were marsupialized, 6 were partly excised and drained, and 1 cyst was malignant and

Fig 6. Further dissection of the cyst abandoned at this point because of dense adhesions to the middle colic artery.

Fig. 7. Cyst has been opened and aspirated revealing smooth lining without papillary growths.

Fig. 8. Cyst wall held with forceps while gauze pack is inserted.

inoperable. In 1935 Kirschner reported an anastomosis of a cyst to the duodenum. Neuffer in 1939 anastomosed a cyst to the gall bladder without ligating the cystic duct. One of us (KAM) (24) reported 13 cases in 1939 and in 3 of these the cyst was successfully anastomosed to the gall bladder the technique described by Neuffer being used. Pinkham in 1939 reported 10 pseudocysts all of which were marsupialized successfully.

More recently Cheaterman in 1943 reported a successful anastomosis of a pseudocyst to the jejunum. In 1946 Adams and Nishijima reported 6 pseudocysts. Two of these were completely excised, 1 was anastomosed to the jejunum, 2 were drained externally and one was first drained externally and the fistula subsequently implanted into the jejunum. Carter and Slattery in 1947

reported 2 cases in which a pseudocyst was completely excised and a third case in which the cyst was anastomosed over a T tube to an accidental rent in the common duct.

In our series of 31 cases a total of 33 operative procedures were performed, one patient undergoing 3 procedures. The types of procedures which were employed are as follows: marsupialization, 25 cases; cystocholecystostomy, 4 cases; cystojejunostomy, 2 cases; complete excision, 2 cases.

RESULTS OF SURGICAL TREATMENT

The results of surgical treatment were analyzed from the standpoint of morbidity, metabolic disturbances and mortality. They will be discussed in that order.

Morbidity. In the 2 cases in which the cyst was completely excised the postoperative course was uneventful and the patients were discharged in 2 and 3 weeks respectively. These cases were considered satisfactory cures.

Cystocholecystostomy was performed in 4 cases of which 3 made an uneventful recovery. They had an average postoperative hospital stay of 18 days. Follow-up studies were made on these 3 patients. One patient, a 64-year-old female, died 1 month after operation of a cerebral hemorrhage. Examination of the cyst at autopsy revealed about 500 cubic centimeters of fluid still present in the cyst which originally contained 2000 cubic centimeters. The second patient who had recovered uneventfully was symptom free when seen 3 months later. A barium meal at this time

Fig. 9. Cyst marsupialized by suturing cyst wall, the peritoneum and posterior rectus sheath, A.

failed to demonstrate the cyst. The third patient in this group was readmitted 5 months later with abdominal pain tenderness and fever but no mass was apparent either on physical or roentgen examination. The patient refused further treatment after 2 weeks and left the hospital with residual tenderness and a low grade fever. The remaining case one in which the cystocholecystostomy was performed after an unsuccessful marsupialization 3 weeks previously (Case 14 Table II), had a stormy postoperative course. The cyst drained poorly and remained palpable while the patient had a high fever and foul stools. Two weeks after cystocholecystostomy the cyst was marsupialized again.

The morbidity in the 2 cases where cystojejunostomy was performed was severe. One patient developed a fecal fistula on the tenth postoperative day and died 1 month later of sepsis and debility. The other patient ran a febrile course until he died, 10 weeks after surgery. Autopsy revealed a suppurative pancreatic pseudocyst with a purulent peritonitis and an early malignant cholangioma of the liver.

Marsupialization was associated with a moderate morbidity as evidenced by the summary in Table II. The average duration of the drainage in the 21 patients who survived the procedure was 7.2 weeks. One patient (Case 16 Table II) whose cyst had ruptured preoperatively developed a postoperative fecal fistula and the drainage persisted for 1 year.

That marsupialization is frequently the safest and most expedient procedure is illustrated by Figures 4 to 10 (retouched photographs). In this case (operated upon by Dr. Peter A. Rossi) complete excision was abandoned for marsupialization because of dense adhesions and adventitious blood vessels. The patient (Case 22 Table II) made an uneventful recovery.

Metabolic disturbances. No evidence of metabolic disturbance was noted in the cases in which the cyst was completely excised or anastomosed to the gall bladder. The deaths which occurred in cystojejunostomy were related to infection and overwhelming sepsis rather than to metabolic causes. That fluid,

*Cyst was marsupialized and then the fistula was anastomosed to the gall bladder and then marsupialized again.

electrolyte and nitrogen balance can be markedly disturbed in cases in which marsupialization has been performed is evidenced by Case 10 Table II. Detailed data regarding this case are presented to illustrate how profound these losses may be and what measures may be used to overcome them.

This patient was a 49 year old white female who had been struck in the abdomen during an altercation 10 days before her admission to the hospital on August 1, 1915. Following this blow she experienced epigastric pain and vomiting. The patient noted the development of a mass in the left hypochondrium which was verified on physical examination. The abdomen was tender and distended. The

These data were previously published by Dr. W. S. Hoffman, in *Surgical Clinics of North America* February 1947, page 217.

red cell count was 3,700,000 and the leucocyte count was 14,500. The urine was scanty and concentrated. No preoperative x ray films were taken and the preoperative diagnosis was ruptured spleen. Operation was performed on the day of admission and a large pseudocyst was marsupialized.

Postoperatively a continuous suction apparatus was inserted into the marsupialized cyst to protect the abdominal wall and drainage from the cyst was collected. In spite of the daily administration of intravenous fluids on August 10 (10th postoperative day) there was an obvious hemococoncentration as evidenced by the low plasma volume and a low serum sodium due to the loss of a large amount of alkaline pancreatic fluid containing sodium bicarbonate. The sodium loss decreased the alkaline reserve and lowered the plasma carbon dioxide combining power resulting in a mild acidosis. The hemococoncentration and low plasma volume caused a retention of nonprotein nitrogen and a prerenal azotemia.

At this point, approximately 7000 cubic centimeters of 0.45 saline in 2.5 per cent dextrose were given during the next 3 days along with liquids and salt orally. On August 14 the plasma volume and serum sodium had been greatly restored by this therapy and in spite of profuse drainage from the cyst, a marked diuresis had been produced which resulted in the excretion of the previously retained nitrogen (Table III). The sodium replacement bolstered the alkaline reserve and elevated the carbon dioxide combining power. At this time with adequate hydration the decrease in total plasma protein became apparent and the patient was placed on low protein diet for 7 days to assay the minimal

protein requirements. Table IV shows the negative nitrogen balance during the period between August 14 and August 21 which was presumably due to the excretion of previously retained nonprotein nitrogen. On August 21 a high protein diet was instituted. After 14 days September 4 the plasma volume as the total circulating protein showed remarkable increments and a positive nitrogen balance was reestablished. The patient's clinical improvement closely paralleled the changes in the blood chemistry.

Mortality. The mortality rates are presented in Table V. No deaths occurred in the cases where complete excision or cystocholecystostomy was performed. A 100 per cent mortality rate was associated with cystojejunostomy because of infection in the cyst, leakage at the suture line, fecal fistula, and peritonitis. Four deaths occurred in the 23 cases in which the cyst was marsupialized with a mortality rate of 16 per cent. These cases have been divided into group A in which the cyst was unruptured preoperatively and group B in which the cyst had ruptured preoperatively and an emergency operation was performed. Of the 21 cases in the unruptured group (A) one surgical death occurred as a result of a massive postoperative atelectasis on the day after surgery (4.8 per cent mortality rate). One patient in this group died 4

TABLE IV.—EFFECT OF HIGH PROTEIN DIET ON CIRCULATING PROTEINS

months after surgery and autopsy revealed a malignant cystadenoma. The 4 cases in the ruptured group (B) had a mortality rate of 75 per cent because of the associated peritonitis and shock.

DISCUSSION

As Archibald and Kaufman stated it is often impossible to distinguish between a pseudocyst and a true cyst. Since the principles of treatment of a true retention cyst do not differ from those of a pseudocyst accurate differentiation is not mandatory. However it is important to differentiate pseudocysts from proliferation cysts and cystadenomas which are neoplastic in character. To this end all pancreatic cysts should be opened after aspirating the contents and the interior and lining of the cyst carefully inspected. It is our opinion that these neoplastic cysts should be completely excised where technically possible. On the other hand Carter and Slattery have recommended marsupialization of proliferative cysts to permit destruction of the epithelial lining with radium or sclerosing agents.

The analysis of the mortality rates of the surgical procedures used suggests that complete excision might be the treatment of choice since the morbidity was negligible and no deaths resulted. However it should be pointed out that complete excision is usually feasible only in the smaller pseudocysts because the larger cysts are fixed by dense adhesions. Judd Mattson and Mahorner reported 7 cases in their series of 47 in which cysts ranging from 6 to 10 centimeters in diameter were completely excised. Carter and Slattery recommended complete excision of pseudocysts but in 2 of their cases an opening was inadvertently made in the common duct during dissection of the dense adhesions and in a third case large adventitious blood vessels on the posterior wall of the cyst caused trouble some hemorrhage from the bed of the pancreas.

Although complete excision is usually reserved for smaller cysts even in these cases the procedure is not without some hazards. Trauma to the pancreas during the excision of the cyst may cause an acute pancreatitis or a pancreatic fistula. Maingot states the mor-

TABLE V — MORTALITY OF SURGICAL PROCEDURES

Type of operation	Number of cases	Deaths	Mortality per cent
Complete excision of cyst		0	
Cystocholecystostomy	4		
Cystojejunostomy			100
Marsupialization of a. Unruptured cyst		2	4.8
b. Ruptured cyst	4	3	75

* These cases were published by John Koucky et al. Surg. Gyn. Obst., 24: 73, 1917.

tality rate of excision of a cyst ranges between 10 and 25 per cent if the cyst is successfully removed. A mortality rate of 55 per cent is given by the same author when an unsuccessful attempt at excision was made.

Cystocholecystostomy like complete excision had no immediate surgical mortality associated with it. But in spite of this several objections to this procedure present themselves. Incomplete emptying of the cyst was noted in 2 cases. In one of these cases the patient was reoperated upon and the cyst was marsupialized in the other case the patient died of a cerebral hemorrhage a month after surgery and at autopsy 500 cubic centimeters of bile and mucin were present in the cyst.

The failure of the cyst to empty completely is understandable when one considers that the cyst wall contains no smooth muscle and hence lacks contractile power. It is therefore dependent upon gravity for drainage. Incomplete emptying of the cyst leaves open the possibility of a traumatic rupture of the cyst with its attendant high mortality. A further objection to the creation of a large diverticulum of the biliary system by this procedure is the stasis of bile with activation of the enzyme lipase and subsequent fat necrosis. This last objection could be overcome as one of us (KAM 24) suggested in an earlier paper by using the technique of Walzel, in which a complementary ligation of the cystic duct is performed.

Since biliary tract disease is frequently associated with pseudocysts a Graham Cole gall bladder visualization should be performed to determine the function of the gall bladder in those cases in which a cystocholecystostomy is contemplated.

Cystojejunostomy was performed in 2 cases in this series with death occurring in both cases. Better results with this procedure were obtained by Adams and Nishijima who reported its successful employment in a pseudocyst and also in a papillary cystadenoma where it served as palliation. Follow up studies on these 2 patients 3 months later revealed them to be symptom free and when a barium meal was given, no barium entered either of the cysts. When a postoperative barium meal was given to one of our patients who ran a septic course after a cystojejunostomy the barium did enter the cyst. Subsequent autopsy of this patient showed a suppurative in the cyst and peritonitis. This evidence suggests that the creation of a large jejunal diverticulum into which food can pass and accumulate is potentially dangerous. An additional hazard in cystojejunostomy is leakage at the suture line which occurred in our second case and caused a fecal fistula and death from peritonitis. Finally the ability of enterokinase and bile to activate the pancreatic enzymes trypsinogen, chymotrypsinogen and lipase may cause acute pancreatitis, and fat necrosis.

Marsupialization in our series was performed with a low mortality rate (4.8%) in the unruptured cysts. This compares with the 7.6 per cent mortality reported by Babcock. One of the objections raised to marsupialization is the development of persistent fistulas which occur in 15 per cent of cases according to Babcock. In our cases the drainage persisted for an average of 7.2 weeks and no persistent fistulas developed in so far as the follow up study could ascertain.

A persistent fistula if it should develop may be treated by medical or surgical measures. Among the medical measures employed Comfort Osterberg and Priestley reported that ephedrine sulfate, $\frac{1}{4}$ grain, given subcutaneously before a meal reduces the volume of secretion from a pancreatic fistula by 50 per cent. The concentration and total bicarbonate and total output of lipase were also reduced while amylase was not affected. They also noted that atropine sulfate $\frac{1}{75}$ grain given subcutaneously before a meal reduces the volume of fistula secretion by reducing

gastric motility and secretion and thus indirectly decreasing the secretion liberated. Craft stated that ephedrine sulfate like epinephrine, decreased pancreatic secretion by its vasoconstrictive action on the pancreatic arterioles.

Other nonoperative measures in the treatment of a pancreatic fistula are based on the use of irritants to cause the proliferation of granulation tissue with eventual fibrosis of the fistulous tract. In this connection, Judd (16) stated that the absence of an epithelial lining in the cyst favored the formation of granulation tissue in response to irritants. Sodium morrhuate packs were placed in a marsupialized cyst by Gordin with complete healing in 18 days. Radium was used by Hamilton without marked improvement in the fistula. Roentgen therapy was used successfully by Culler in 2 cases of persistent fistula. Maingot states that if the fistula does not close within 6 weeks and most fistulas do tend to close spontaneously operation should be advised. The operative treatment of persistent fistula as reported by Lahey (17) is the transplantation of the fistula into the jejunum. Maingot states that this is a relatively safe surgical procedure as evidenced by the 3.8 per cent mortality in the 26 cases of pancreaticojejunostomy and pancreaticogastrostomy collected and reported by Lahey.

The postoperative care of a patient with a marsupialized cyst requires special attention to fluid, electrolyte and nitrogen balance. As Case 10 Table II illustrated the fluid and electrolyte loss may be so great as to produce a state of hemoconcentration with azotemia and acidosis. This may be accompanied by a profound protein loss and a negative nitrogen balance. The replacement of the fluids, electrolytes and protein with the re-establishment of a positive nitrogen balance indicates that these occasional complications can be successfully combated even when severe, if they are recognized early and treated vigorously. These postoperative measures have greatly reduced the hazards which formerly attended marsupialization in some instances. A further adjunct to postoperative care is the use of bronze or aluminum paste on the skin and continuous suction in the cyst to prevent the drainage fluid from excoriating the skin.

Ruptured pseudocysts have a mortality rate of 75 per cent largely because of the resulting peritonitis and shock. This alarming mortality rate emphasizes the importance of early elective surgical intervention in pancreatic pseudocysts to preclude the possibility of rupture of the cyst.

SUMMARY

1 A report is given of 31 cases of pseudocysts of the pancreas which were treated surgically

2 Severe blunt abdominal trauma was an etiological factor in 51.6 per cent of cases cholecystitis cholelithiasis, and pancreatitis were factors in 16.1 per cent of cases

3 The amount of fluid found in the cysts ranged between 15 and 7000 cubic centimeters and averaged 2686 cubic centimeters

4. In 13 of 14 cases in which a barium meal was given displacement of the stomach was shown and in 6 of 7 cases in which a barium enema was given displacement of the transverse colon was shown where these procedures were utilized.

5 Complete excision of a small pseudocyst was done in 2 patients without a mortality. Cystocholecystostomy was performed in 4 patients without a mortality. Marsupialization was performed in 21 unruptured cysts with a mortality rate of 4.8 per cent and in 4 ruptured cysts with a 75 per cent mortality rate. Cystojejunostomy was performed in 2 cases with a 100 per cent mortality rate

6 Following marsupialization in 1 patient, profuse drainage from the cyst caused hemocoagulation mild acidosis azotemia and a negative nitrogen balance. Energetic administration of fluid electrolytes and a high protein diet corrected these complications

7 The average duration of drainage from the cysts following marsupialization was 7.2 weeks and, in no instance did a persistent fistula develop

ENDOMETRIOSIS—ITS SURGICAL SIGNIFICANCE

A Critical Analysis of 179 Cases

FRANCIS J. KELLY M.D., Amarillo, Texas, and K. RAMSAY SCHLADEMAN M.D. Fort Wayne, Indiana

ENDOMETRIOSIS is generally considered to be a lesion containing ectopic uterine mucosa.

Many authors recently have confined their remarks to the extrauterine manifestation and for this reason it was felt worth while to study the problem in its entirety rather than limit our considerations. Though cognizant of the very probable difference in origin of the two types (intrauterine and extrauterine) we were especially interested in two factors which could be affected by endometriosis regardless of location. One is the too frequently emphasized symptom of progressive dysmenorrhea and the second is the incidence of absolute fertility following conservative surgical management as determined by careful follow up study.

In 1896 von Recklinghausen enunciated his theory of misplaced derivatives of the wolffian or muellerian duct, which might explain the presence of ectopic endometrium. Cullen's monumental work in 1908 followed, but it was not until 1921 subsequent to the excellent study of Sampson (15) that the lesion became of widespread clinical significance. At the present time there remain many theories concerning the origin of endometriosis, no one adequately explaining the diverse manifestations. It is increasingly evident that the disease may be due to several factors. The most widely accepted suppositions include the following:

1. The embryonic theory oldest of all is based on the fact that the epithelium of the pelvic peritoneum fallopian tubes uterus and germinal epithelium of the ovary have a common origin in the celomic epithelium and under certain conditions the embryonic rests

contained in the pelvic peritoneum reproduce endometrium.

2. The metaplasia theory attempts to explain endometriosis by holding that the peritoneum is stimulated to form glands resembling endometrium. The greatest objection to this very convenient explanation is the necessity of assuming metaplasia.

3. Sampson's (16) view and perhaps the most widely known postulates that endometrial cells escape by way of the fallopian tubes, at menstruation and are deposited on the ovary or pelvic peritoneum and develop as an implant. The chief objection to this theory is its failure to explain extraperitoneal lesions, in the bladder inguinal glands, or as seen from 1 case in this series, in the umbilicus.

4. Recently there has been renewed interest in lymphatic transportation as advanced by Halban in 1924. Sampson (17) in 1927 demonstrated endometrial fragments in the veins of the uterus.

5. Finally surgical implants are occasionally seen following pelvic operations and one such instance is reported in the present series.

MATERIAL

During 1,991 consecutive abdominal gynecologic operations at Scott and White Clinic, 179 (8.9 per cent) histologically verified cases of endometriosis were found and these together with follow up study form the basis for this paper. The average age of these patients was 38 years the youngest 20 and the oldest 65 years.

Fallas and Rosenblum report 1.62 per cent endometriosis in 15,975 gynecologic laparotomies done in two Los Angeles private hospitals between 1930 and 1939. Sanders encountered the lesion in 17 per cent of 700 laparotomies for gynecologic diseases. Meigs (12) on the other hand found that 28 per cent

From the Departments of Surgery and Pathology Scott and White Clinic, Temple, Texas.

Dr. Kelly is chief surgeon, Veterans Administration Hospital, Amarillo.

Fig. 1. Multiple sites of implantation as seen at operation. Note typical puckering and dense, solid strands.

of 400 private patients and 5.8 per cent of 400 patients at the Massachusetts General Hospital showed extrauterine endometriosis microscopically. It is difficult to determine the incidence of endometriosis as many of the tumors are small and easily overlooked in routine examinations due to the multiplicity of sites of invasion (Fig. 1). The serious consequences of the unrecognized tumor requires no elaboration and it becomes imperative for the surgeon to search carefully and to recognize the characteristic bluish black dots on the pelvic peritoneum.

APPEARANCE

Endometriosis presents a rather typical gross appearance best referred to as 'puckered' areas especially in the advanced stages. Early manifestations are likewise characteristic in their 'blueberry spot' form. When these cysts perforate or are ruptured, a black, tarry irritating fluid may be scattered over the contiguous organs. Just as the cysts react to ovarian stimulation at the menstrual phases much the same as normally situated endo-

metrium so at the menopause whether natural or artificial, endometrial lesions will recede.

The presence of adhesions due to endometriosis are frequent and when once seen should rarely be confused with those caused by other pelvic inflammatory disease. The adhesions of the latter are generally broad and labile and easily torn while those of the former are tough and solid with a tendency to strand formation. Fixed retroversion of the uterus should always cause the surgeon to suspect endometriosis. Chocolate cysts of the ovary are less likely to be overlooked however we believe that it is imperative that a microscopic section be performed at once if radical surgery is contemplated to exclude simple hemorrhagic cysts.

PATHOLOGY

The microscopic picture of extrauterine endometriosis is that of well defined endometrial glands surrounded by endometrial stroma varying in amount from little or none to a definitely stromal collar. Those implants influenced by hormones contain extravasated blood and hemosiderin laden phagocytes.

TABLE I.—SYMPTOMATOLOGY

	No. of cases	Percentage
Acquired dysmenorrhea	86	48.3
Severe	34

Premenstrual discomfort		
Painful scar with menstruation		

The microscopic picture of intramural endometriosis or adenomyosis consists of well defined epithelial islets surrounded by varying amounts of stroma within the myometrium. Serial study of such implants will show them to be continuous with the endometrium and the formation is that of a crypt like structure extending into the myometrium (1-13). The adenomyoma of Cullen is a variant of intramural endometriosis in which the epithelial implants are incorporated in a leiomyoma.

The diagnosis of adenomyosis in this series was based on the finding of endometrial inclusions in the myometrium a distance of at least the diameter of a full low power field from the base of the endometrial lining of the uterine cavity. Serial study would undoubtedly have shown these areas to be distal prolongations of cryptic invaginations from the endometrium.

SYMPTOMATOLOGY

The clinical diagnosis is admittedly difficult because of the variable history symptoms, and physical findings. There is one symptom however toward which particular attention was directed in this review. This is the factor of increasing or progressive dysmenorrhea. Though King and Fiddes in 1929 pointed out

this symptom as being characteristic, the majority of writers on this subject, we feel, do not emphasize this factor sufficiently. We agree with Fallon, Broonan and Moran that, when present, the symptom should be considered pathognomonic. In a review of 200 articles, these authors found only 12 who emphasized this symptom.

As noted in Table I, 1 out of 3 patients complained of increasing dysmenorrhea. This takes on added significance when it is noted that only 48.3 per cent complained of the repeatedly emphasized symptom of acquired dysmenorrhea, which, though important is part of the symptom complex of many disorders of the female genital organs. The distinction is important and should not be confused.

With a complaint of painful periods it should be determined whether or not the dysmenorrhea has been present since menarche or has been acquired following normal menstrual cycles. In most cases of endometriosis the latter situation will have prevailed. If the patient further states that her dysmenorrhea, acquired or not, has progressively become more intense with each succeeding cycle the diagnosis rests with endometriosis. We know of no other condition in which this symptom is present. The rate of progression is variable and many patients take several years before the severity increases sufficiently to bring them to their physician. On the other hand, the patient may have had painless periods for years may develop dysmenorrhea which becomes more intense with each succeeding period, and may require treatment within a very few months from the initial onset. Too the length of time the patient may complain of pain during each period will vary though as a rule the longer the duration of progression the more extended will be the dysmenorrhea at any particular period. In several instances patients were without pain for only a few days in each complete cycle.

One out of 4 complained of an increased amount of flow at the menstrual period. Low backache was a relatively frequent complaint during menses, though in no appreciably greater incidence than that found in the average female with pelvic complaints. Twenty

TABLE II — CLINICAL DIAGNOSES

	No. of cases	Percentage

five patients on the other hand gave no symptom referable to menstruation.

Thirty-two patients (17.9 per cent) had lesions of the rectosigmoid (Fig. 2) but only one half of these gave a history of gastrointestinal disturbance. One of these however had a partial intestinal obstruction while the remainder complained of painful defecation, abdominal distention or flatulence immediately prior to or during the menstrual period. Masson found endometriosis of the sigmoid and rectovaginal septum in 34 of 576 cases or in 5.9 per cent while Sanders found that 12 per cent had involvement of the sigmoid.

Dyspareunia was a complaint of 15 patients and this of course must be considered in the high rate of relative sterility in this group of patients.

DIAGNOSIS

It is a regrettable fact that endometriosis in spite of its prevalence and importance has a low diagnostic index. In this series the diagnosis was correctly made in 14.5 per cent. In this connection it is to be noted that had the symptom of increasing dysmenorrhea been regarded as indicative of endometriosis as we now believe it should be, the diagnostic index would have more than doubled to 33.5 per cent—the percentage of patients with this complaint. Uterine displacement (prolapse, retrocession, retroversion) is a common finding in the presence of endometriosis, often due to the inflammatory reaction and subsequent adhesions induced by the peritoneal implants. A fixed retroversion should at once cause the

Fig. 2. Characteristic appearance of endometriosis on the sigmoid. The uterus has been removed.

physician to consider endometriosis. A summary of the clinical diagnoses made in this series is presented in Table II.

LOCATION OF ENDOMETRIOSIS

Endometriosis is extremely rare above the umbilicus. In this series 1 endometrioma was found in the umbilicus. The distribution of the lesions follows that found in most large series (Table III). The peritoneal surface of the uterus was the most common site, the lesion being present in 64 patients. The wall of the uterus was next in frequency with 46 patients having diffuse adenomyosis and 11 found to have intrauterine endometriomas. The cul-de-sac was involved in 42 patients and in most cases the result was a marked retrodisplacement. Situations where heterotopic endometrium was found in the group of patients included in this study are consolidated on the illustration in Figure 3.

Fig. 3. Distribution of ectopic terine mucosa in this series. The arrow indicates the sites of in situ. The figures indicate the number of cases in which the lesion was found at each location (Table III).

In 1 patient the lesion was found in a laparotomy wound. Keene and Kimbrough found 1 in this location in a series of 118 cases, while Jenkinson and Brown reported 3 in 117 cases. In our group 81 patients had been subjected to a previous abdominal gynecologic operation. It is evident then that manipulation or trauma of the pelvic organs at the time of surgery can be a direct etiologic factor in the spread of endometriosis. That the original production of endometriosis can be influenced by manipulative procedures must be considered for in this series a relatively large number of patients had undergone previous surgery (45.3 per cent). The average number of years since that surgery was 8.4 years.

ASSOCIATED PELVIC CONDITIONS

A characteristic feature of endometriosis is the frequent occurrence of pathological conditions in association with the lesion. Displacement of the uterus was relatively common, particularly retroversion (Table IV). One hundred and forty-eight patients had some type of displacement not considered normal. Leiomyoma occurred in 88 (49.4 per cent) of 178 patients (1 previous hysterecto-

my). Counseller reported 54.5 per cent of 308 patients and Keene and Kimbrough found 55.4 per cent with myoma. Two patients in our group had endometriosis concomitant with adenocarcinoma of the uterus. An interesting finding in view of the relative sterility of the patient with endometriosis was 1 patient in whom the lesion was found during surgery for tubal pregnancy.

SURGICAL PROCEDURES

The choice as to the correct type of operation to be employed is not always clearly defined. The extent and location of the lesions are of primary consideration though the age of the patient is a factor especially in those over 40 years. The problem however will always be present as endometriosis is not a disease of old age but rather a disease affecting a large percentage of women during their reproductive life. Most surgeons are in agreement with the statement that it is well worth while to spend 30 minutes or more if necessary excising individual lesions than to perform the more radical procedures. That this conservatism when possible will bear fruit will be shown later (Table VI).

In our series it was necessary to do the more radical procedures in 132 patients. One hundred and thirty of these required hysterectomy (72.6 per cent) while the remaining 2 patients were treated by bilateral oophorectomy alone.

As might be expected with these lesions, lysis of adhesions of more than minor nature was performed in a relatively large number of cases (36.9 per cent). It is not surprising then

TABLE IV — OPERATIVE FINDINGS

	N	of cases	Percentage

to find that of the 48 patients in whom hysterectomy had not been performed all but 1 required uterine suspension (Table V)

No patient received presacral resection though occasionally considered as the experience at this clinic has been that surgical replacement of the uterus has satisfactorily relieved the symptoms arising from displacement

FERTILITY

Perhaps the most important factor in a discussion of endometriosis is its relation to fertility both prior to and following surgery. This is of special consideration to the patient in the child bearing age. If conservative surgery is to be practiced what chance will the patient have of becoming pregnant following conservation of the reproductive organs? We believe it is sufficient to warrant the plea to err on the side of conservatism rather than to employ specific treatment and destroy ovarian function at the time of surgery.

If symptoms persist the diagnosis having been made roentgen therapy may then be applied to one or both ovaries. In our series this has been necessary in 7 patients with relief of symptoms in all cases.

Most observers conclude that 10 to 15 per cent of marriages do not result in pregnancy. Reynolds and Macomber stated that the per-

TABLE V — MAJOR OPERATIVE PROCEDURES

Unilateral oophorectomy	26	14	5
Bilateral oophorectomy	2		
Excision of umbilicus	1		
Release of obstruction	1		

centage of sterile marriages in Massachusetts was not lower than 10 and probably not higher than 13 per cent. In this study we have used the figure of 88 per cent as representing normal fertility.

Under the heading of absolute fertility are included only those patients who had actually been pregnant prior to surgery. Those patients however married less than an arbitrary 5 year period prior to treatment were excluded. Thus it was determined that of 166 patients only 46.4 per cent had ever become pregnant. Jenkinson and Brown found 41 per cent had been pregnant. Keene and Kimbrough reported 59.1 per cent while Meigs (12) found 65.7 per cent fertility.

The relationship between endometriosis and delayed or infrequent childbearing is well known. Cause and effect however have yet to be adequately defined. Certainly as Meigs (11) has stated women with a stigma of underdevelopment (and many of these do not marry because they are also underdeveloped sexually) and well developed women who put off marriage too long or who try to put off pregnancy until well after married life has begun are likely to develop endometriosis. On the other hand the presence of endometriosis may result in marked retroversion, dyspareunia, pelvic inflammation and intrauterine endometrioma which in themselves are not

TABLE VI — RELATION OF ENDOMETRIOSIS TO PREGNANCY

Average age (all patients)	38 years
Normal fertility	88 per cent
Absolute fertility in this series (excluding those married less than 5 years)	46.4 per cent
No. of patients relatively fertile following surgery	38
Average age	31 years
Absolute fertility (following surgery)	83.7 per cent
166 patients.	

infrequent causes of relative sterility. Of the 166 patients who had been pregnant prior to surgery the average interval between their last pregnancy and the time of operation was 11 years. Keene and Kimbrough reported the average interval of sterility in 39 patients was 9.5 years.

Following surgery 38 patients in this study could be classed as relatively fertile; that is, pregnancy was both theoretically and practically possible as far as could be determined. The average age of this group of patients was 31 years. It has been possible to follow these patients a minimum of 2 years and a maximum to date of 6 years. Though a longer follow up interval would be desirable, the results during this time serve to re-emphasize the value of conservative surgery whenever possible. Eleven pregnancies have occurred in 23.7 per cent of these 38 patients and all occurred within 4 years following surgery. Two patients have been pregnant twice during this time; neither of whom had previously been pregnant.

SUMMARY

1. A brief résumé of the most widely accepted hypotheses concerning the etiology of endometriosis is presented. It is evident that no one theory adequately explains the variable manifestations.

2. Endometriosis was present in 8.9 per cent of 1991 consecutive gynecologic laparotomies.

3. Progressive dysmenorrhea, when present is pathognomonic of endometriosis. If more

attention were directed toward this symptom the low diagnostic index now prevalent could be appreciably raised.

4. Though radical operative procedures were considered necessary in the majority of these patients, conservatism when possible is justified as indicated by an absolute fertility of 23.7 per cent after conservative surgery had been carried out.

THE ETIOLOGY OF STRESS INCONTINENCE

S RICHARD MUELLNER, M D., Boston Massachusetts

THE precise etiology of exertional incontinence has to date remained obscure. Opinions are still divided on the nature of the lesion responsible for the impaired urinary control. Most authors ascribe stress incontinence to traumatized urethral sphincters as a result of childbirth, others insist that it is caused by obstetrical injury of the bladder supports.

In a previous investigation (4) 95 patients with exertional incontinence and 45 continent multiparas were carefully studied by cystometry, cystoscopy, cystography and urethrography.

These studies failed to reveal a specific lesion of stress incontinence, but made it clear that unless much more was known about the normal mechanism responsible for urinary control, the cause of exertional incontinence could not be detected. Specifically, one had to know how a normal woman initiated and shut off her urinary stream.

This information could not be obtained by cystometry or cystography and urethrography. It was therefore necessary to devise a technique of study which could portray the dynamic events of micturition.

Direct observation of the bladder under the fluoroscope seemed to offer such a possibility and for the past year and a half a study of normal and abnormal micturition in men, women and children was carried out at the Beth Israel Hospital (5). A total of 85 observations have been made to date, 30 of these were of women suffering from stress incontinence.

The technique of study was briefly as follows. The bladder was first filled through a No. 16 French catheter with a contrast medium consisting of a 5 per cent (5%) solution of sodium iodide to which a 20 cubic centimeter ampule of aqueous diodrast (35% by volume) had been added. The catheter was then withdrawn. A filling of the bladder with 200 to 250 cubic centimeters of this mixture was usually sufficient for study in the average case.

Observations were made with the subject supine, standing, and turned to one side or the other. Care was taken to maintain the relationship of the x ray tube to the symphysis pubis so that changes in the position of the bladder resulting from a change of posture could be accurately evaluated.

The effects of coughing and straining on the bladder and on its supports and the events at the beginning of micturition and when the urinary stream was inhibited were then carefully observed. Spot films of the bladder while the patient was in various positions and during micturition were taken from time to time.

A special plastic urinal (Fig. 1) which would not cast an x ray shadow was devised to permit the subject to void while standing.

The precise pathology of exertional incontinence became apparent when the findings in the normal nullipara and in the continent multipara were compared with the observations in women with stress incontinence.

THE ETIOLOGY OF STRESS INCONTINENCE

S RICHARD MUELLNER, M D., Boston Massachusetts

THE precise etiology of exertional incontinence has to date remained obscure. Opinions are still divided on the nature of the lesion responsible for the impaired urinary control. Most authors ascribe stress incontinence to traumatized urethral sphincters as a result of childbirth; others insist that it is caused by obstetrical injury of the bladder supports.

In a previous investigation (4) 95 patients with exertional incontinence and 45 continent multiparas were carefully studied by cystometry, cystoscopy, cystography and urethrogram.

These studies failed to reveal a specific lesion of stress incontinence, but made it clear that unless much more was known about the normal mechanism responsible for urinary control, the cause of exertional incontinence could not be detected. Specifically, one had to know how a normal woman initiated and shut off her urinary stream.

This information could not be obtained by cystometry or cystography and urethrography. It was therefore necessary to devise a technique of study which could portray the dynamic events of micturition.

Direct observation of the bladder under the fluoroscope seemed to offer such a possibility, and for the past year and a half a study of normal and abnormal micturition in men, women and children was carried out at the Beth Israel Hospital (5). A total of 85 observations have been made to date; 30 of these were of women suffering from stress incontinence.

The technique of study was briefly as follows. The bladder was first filled through a No. 16 French catheter with a contrast medium consisting of a 5 per cent (5%) solution of sodium iodide to which a 20 cubic centimeter ampule of aqueous diodrast (35% by volume) had been added. The catheter was then withdrawn. A filling of the bladder with 200 to 250 cubic centimeters of this mixture was usually sufficient for study in the average case.

From the Department of Urology, Beth Israel Hospital, Boston.

Observations were made with the subject supine, standing and turned to one side or the other. Care was taken to maintain the relationship of the x-ray tube to the symphysis pubis so that changes in the position of the bladder resulting from a change of posture could be accurately evaluated.

The effects of coughing and straining on the bladder and on its supports and the events at the beginning of micturition and when the urinary stream was inhibited were then carefully observed. Spot films of the bladder while the patient was in various positions and during micturition were taken from time to time.

A special plastic urinal (Fig. 1) which would not cast an x-ray shadow was devised to permit the subject to void while standing.

The precise pathology of exertional incontinence became apparent when the findings in the normal nullipara and in the continent multipara were compared with the observations in women with stress incontinence.

Fig. 1. Plastic urinal. Note long handle.

Fig. 2. a, C M Nullipara, Recumbent note shape of the bladder base and its position in relation to symphysis pubis. b, Erect note that bladder position is maintained in erect posture. c, During micturition the vertical diameter of the bladder is increased, and the horizontal diameter has decreased. The internal sphincter occupies a somewhat lower position in the pelvis.

Fig. 3. a, Diagram of bladder in nullipara. Dotted line shows change of bladder shape on coughing. Note that bladder base remains steady. b, Note "pointed" appearance of bladder base and descent of internal sphincter with voluntary attempt at micturition. c, Voluntary inhibition of the urinary stream. Arrows point to the direction in which the bladder base is lifted. p t, Urinary stream off. Dotted line shows bladder shape when urinary stream is stopped.

In the normal nullipara while recumbent the bladder has a smooth outline and its base lies just above the symphysis pubis (Fig. 2a). This position of the bladder is maintained when she stands up. On coughing the bladder base does not yield, but the impulse from the increased intra-abdominal pressure is dissipated along the dome and to the sides of the bladder, revealing the excellence of the bladder supports (Fig. 3a).

When she is asked to void, the bladder base can be seen to descend sharply, so that the region of the internal sphincter becomes the most dependent portion of the bladder and assumes a "pointed" appearance (Fig. 3b). This is the first important maneuver in the complex process of micturition, and its significance was

neither known nor appreciated in the past. It is this descent of the internal sphincter which opens it slightly and permits a small amount of the contrast medium to enter the proximal urethra. This is followed by contraction of the detrusor, and uninterrupted micturition then ensues. Once micturition has begun the bladder base returns to a position slightly lower than that of its resting phase (Fig. 3c).

If the subject is now asked to inhibit the urinary stream, she pulls the bladder base up quickly and to a level slightly higher than it had assumed before micturition. The bladder base becomes horizontal and the urinary stream is promptly shut off (Fig. 3c).

In the continent multipara the events are very similar, except that the bladder is some

Fig 4. a left R.G. continent multipara, recumbent. b, Erect note descent of bladder base, indicating laxity of general bladder supports, yet not causing stress incontinence

Fig 5. a left, A.H. multipara, stress incontinence. Recumbent note position and shape of bladder base. b Erect note 'pointing' of bladder base. Internal sphincter has descended. Pointed bladder base is typical of stress incontinence.

what larger and flabbier and the bladder supports are more yielding. The bladder base sinks to a considerably lower position in the standing as compared to the recumbent posture (Fig 4a and b).

On coughing or straining the bladder base descends as a whole with the sudden increase in intra abdominal pressure. These women clearly demonstrate that mere relaxation of the bladder supports does not impair urinary control.

A few points in the observations of women who can control the urine deserve emphasis.

First the bladder base and especially the region of the internal sphincter is in close relationship to the muscles of the pelvic floor. Second these muscles play a very active part in the initiation and in the inhibition of the urinary stream. Third when the continent woman stands up these muscles form a firm support for the internal sphincter and not only take on the added gravitational strain induced by the erect posture which amounts to

10 to 12 millimeters of mercury (6) but they also take up any additional sharp increases in intravesical pressure which result from exertion coughing or sneezing and thus protect the internal sphincter against these stresses.

A review of the anatomy of the muscles of the pelvic floor and especially the contributions made by Thompson, Savage, Holl, Lesshaft and Smith make it clear that it is the pubococcygeus portion of the levator ani and perhaps to a very much lesser extent the deep transverse perineal muscle which play this important part in micturition and in urinary control. These muscles with a somatic innervation are responsible for the descent of the internal sphincter at the start of micturition and they sharply lift the bladder base up to shut the stream off. It is the descent and the opening of the internal sphincter which initiates the reflexes of micturition.

Under the fluoroscope the descent and the pointing of the internal sphincter appear as a downward pull. Actually there are no mus-

Fig. 6. a, left, Diagrammatic representation of stress incontinence. Solid line bladder during recumbency. Dotted line showing minimum descent of internal sphincter which is necessary for micturition.

Fig. 7. a, left, L. G. primipara, life-long stress incontinence unaffected by birth of child. Recumbent note smooth bladder base above symphysis. The internal sphincter is normally shut off. b, Erect, not straining, note "pointing" of bladder base and "funneling" of internal sphincter revealing its congenital callosity.

cles in the pelvic floor or in the perineum which could pull the bladder base down. It is more correct to speak of this maneuver as a 'downward push' and it is brought about by the joint forces resulting from the increased intra-abdominal pressure (the fixation of the diaphragm at the end of a brief inspiration and the contraction of the abdominal muscles) gravity and the relaxation of the muscles of the pelvic floor (3).

In contrast to animals, only erect man has a pelvic outlet which is constructed to cope with the problem of gravity resulting from postural changes.

Erect man thus has a dual mechanism for urinary control. First there is the internal sphincter which in tonic contraction while the detrusor is relaxed effectively shuts the blad-

der off and second the muscles of the pelvic floor. For urinary control in the female the distal two-thirds of the urethra are of no consequence since this much of the urethra can be excised as it usually is for carcinoma of the urethra, without in any way impairing urinary continence (2, 10).

If these important facts are kept in mind the lesion of exertional incontinence becomes at once apparent.

While recumbent women with stress incontinence have a bladder shape very much like that of the continent multipara. On coughing the bladder base makes a considerable excursion downward but the region of the internal sphincter takes up most of this downward thrust and yields even more than the base.

Fig 8 a, left S G nullipara, life-long stress incontinence. Recumbent note smooth bladder base. Internal sphincter shut off normally b Erect arrow points to 'funneling' of internal sphincter

Fig 9 a, left, S H., nullipara who developed stress incontinence after a recent hysterectomy. Recumbent note smooth bladder base. Internal sphincter is normally shut off b, Erect note pointed bladder base and descent of internal sphincter

While lying quietly the internal sphincter is shut off normally showing no evidence of injury or deficiency (Fig 5). When the patient is now made to stand up the bladder assumes an appearance which has been present in every case of incontinence studied by means of this technique and one which can therefore be said to be typical of stress incontinence (Fig 5b). While the bladder base descends as a whole in the erect as compared to the recumbent position it is specifically the region of the internal sphincter which descends most and becomes the most dependent portion of the bladder. The bladder base assumes the 'pointed' appearance characteristic of the bladder poised for micturition. It then takes only very little further descent to open the internal sphincter and to allow a jet of urine to escape. This then is an altogether different base line than

the one which is seen in the continent nullipara or multipara and it is obviously brought about not by a general inadequacy of the bladder support but by a very particular one. In exertional incontinence it is precisely the region of the internal sphincter which is not supported and which permits this sphincter to become dependent so as to give the bladder base its characteristic appearance when the patient stands up. It is for this reason that most women with stress incontinence do not lose their urine when recumbent but lose it when they suddenly increase the intra abdominal pressure while they are up and about.

It has been common experience that women with severe incontinence are apt to lose their entire bladder contents with the initial stress. The fluoroscope reveals why this is so. The supports of the internal sphincter in these

Fig. 6. a, left Diagrammatic representation of stress incontinence. Solid line bladder during recumbency. Dotted line "pointing" of bladder base and descent of internal sphincter when erect. b, Solid line, bladder during erect posture. Dotted line, showing minimum descent of internal sphincter. Such is necessary for micturition.

cles in the pelvic floor or in the perineum which could pull the bladder base down. It is more correct to speak of this maneuver as a "downward push" and it is brought about by the joint forces resulting from the increased intra-abdominal pressure (the fixation of the diaphragm at the end of a brief inspiration and the contraction of the abdominal muscles) gravity and the relaxation of the muscles of the pelvic floor (3).

In contrast to animals only erect man has a pelvic outlet which is constructed to cope with the problem of gravity resulting from postural changes.

Erect man thus has a dual mechanism for urinary control. First there is the internal sphincter which in tonic contraction while the detrusor is relaxed effectively shuts the blad-

der off and second the muscles of the pelvic floor. For urinary control in the female the distal two-thirds of the urethra are of no consequence since this much of the urethra can be excised as it usually is for carcinoma of the urethra without in any way impairing urinary continence (2, 10).

If these important facts are kept in mind the lesion of exertional incontinence becomes at once apparent.

While recumbent, women with stress incontinence have a bladder shape very much like that of the continent multipara. On coughing the bladder base makes a considerable excursion downward but the region of the internal sphincter takes up most of this downward thrust and yields even more than the base.

Fig 8 a, left, S G nullipara life long stress incontinence. Recumbent note smooth bladder base. Internal sphincter shut off normally b Erect arrow points to "funneling" of internal sphincter

Fig 9 a left, S H nullipara who developed stress incontinence after a recent hysterectomy. Recumbent note smooth bladder base. Internal sphincter is normally shut off b Erect note pointed bladder base and descent of internal sphincter

While lying quietly the internal sphincter is shut off normally showing no evidence of injury or deficiency (Fig 5). When the patient is now made to stand up the bladder assumes an appearance which has been present in every case of incontinence studied by means of this technique and one which can therefore be said to be typical of stress incontinence (Fig 5b). While the bladder base descends as a whole in the erect as compared to the recumbent position it is specifically the region of the internal sphincter which descends most and becomes the most dependent portion of the bladder. The bladder base assumes the pointed appearance characteristic of the bladder poised for micturition. It then takes only very little further descent to open the internal sphincter and to allow a jet of urine to escape. This then is an altogether different base line than

the one which is seen in the continent nullipara or multipara and it is obviously brought about not by a general inadequacy of the bladder support but by a very particular one. In exertional incontinence it is precisely the region of the internal sphincter which is not supported and which permits this sphincter to become dependent so as to give the bladder base its characteristic appearance when the patient stands up. It is for this reason that most women with stress incontinence do not lose their urine when recumbent but lose it when they suddenly increase the intra abdominal pressure while they are up and about.

It has been common experience that women with severe incontinence are apt to lose their entire bladder contents with the initial stress. The fluoroscope reveals why this is so. The supports of the internal sphincter in these

women do not have enough tonicity to pull the bladder base up all the way and to level it off in order to inhibit the urinary stream and since these women fail to lift the bladder base up sufficiently high micturition goes on to completion once it has ensued.

Functional incontinence in nulliparous women has always been puzzling. Two such cases were studied fluoroscopically and the particular cause of stress incontinence in these women also could be demonstrated. In both women the internal sphincter was perfectly normal when they were lying down (Figs. 6 and 7). When they were made to stand up the bladder base was still well supported but the internal sphincter now formed a deep dimple demonstrating a congenital weakness of the internal sphincter and its supports. When these women were asked to cough the downward pull on the funneled sphincter permitted a jet of urine to escape.

These cases once more demonstrate the fact that a perfectly well supported bladder base does not guarantee urinary continence in the erect posture if the support of the internal sphincter is incompetent.

It is well known that women may develop stress incontinence for the first time after a hysterectomy or after a cystocele repair. This embarrassing situation has been difficult to explain. One such case came to study.

Mrs. F. H. BROWN, 3505 N. 53rd St., Milwaukee, Wis., had a hysterectomy elsewhere in 1910. Following this operation she developed severe stress incontinence. The physical and pelvic examinations were not remarkable. The fluoroscopic study of her bladder (Fig. 9) revealed the typical lesion of stress incontinence.

Just how a hysterectomy in some cases will interfere with the support of the internal sphincter is not clear at present. Further investigation of this problem is planned.

SUMMARY

The mechanism of urinary control in the normal female consists of two parts: the internal sphincter and the pubococcygeus portion of the levator ani. The latter is particularly important for urinary control in the erect posture.

Functional incontinence results from failure of the pubococcygeus to support the bladder neck.

ANTERIOR POLIOMYELITIS, EARLY AND LATE ELECTRICAL STIMULATION OF THE MUSCLES

STAFFORD L. OSBORNE, Ph D, A J KOSMAN, Ph D, H D BOUMAN, M D,
ROBERT T McELVenny, M D., and A C IVEY, Ph D., M D., Chicago, Illinois

SACHS in 1910 wrote that the aim of therapy for the patient with anterior poliomyelitis should be to exercise muscles which cannot be exercised voluntarily. For this he recommended the use of a form of electrical current which would yield the best contraction with a current of moderate strength. Williams and Levick concurred and maintained that the treatment should be applied early after the diagnosis of the disease.

From 1939 to 1946 a series of articles appeared (5, 14, 16-21, 25, 28) which present evidence clearly establishing that the appropriate electrical stimulation of denervated muscle in laboratory animals retards the loss of weight and strength. However few observations have been made on man. Doupe, Barnes and Kerr obtained no effect in man when the rate of recovery of muscles after suture of the radial nerve was followed with and without galvanism. In the light of present knowledge the treatment used was inadequate and the criterion used was inappropriate. Shirley Jackson in 1945 in tensively treated patients with ulnar paralysis and obtained favorable results. Liu and Lewey reported that they obtained results similar to those of Jackson though in their cases the muscle atrophy was far advanced (6 to 20 months) when treatment was started and they treated their patients for only a relatively short period.

In 1940 an investigation was started to ascertain the therapeutic value of electrical stimulation of denervated muscle. It was felt that no previous investigator except Fischer

had used an optimal stimulus on the basis of what was known regarding the electrical excitability of muscle. In the first phase of this investigation a systematic search was made to find the wave form, frequency and intensity of the current most suitable for stimulating and retarding atrophy of denervated skeletal muscle. The second phase involved a controlled study on animals to ascertain the various factors other than the nature of the current which might retard the rate of loss of weight and strength of denervated muscle. The present article represents the application of our observations on animals to patients with anterior poliomyelitis. The results on patients with a muscle denervated by section of a nerve will be reported later.

METHODS

Late group Because patients were not available in the early stage of the disease when the experiment was started it was necessary to select patients who had had anterior poliomyelitis for some time. However this was an advantage because it enabled us to work out the technique to be used in stimulating the paralyzed or paretic muscles. It was important to have our technique mastered before undertaking treatment in the early stage. Thirteen late patients were selected for treatment. These patients had had the disease for periods ranging from 6 months to 6 years.

Early group Later when the epidemic of 1946 occurred in Chicago it was possible to select 7 patients as soon as they entered the Chicago Municipal Contagious Hospital and the diagnosis of anterior poliomyelitis was made. The same number of patients were selected as a control group. The selection of both groups was made on the basis of the muscles involved and the apparent extent of the paralysis. At this stage of the disease it is obvious that such a selection is very arti-

Aided by a grant from the National Foundation for Infantile Paralysis, Inc.

Dr. Bouman is now at the Department of Physical Medicine, University of Wisconsin.

Dr. Ivey is now at the University of Illinois College of Medicine, Department of Clinical Science.

Fig. 1. Tensity-frequency curves of right hamstrings, patient 7, showing the change in the shape of the curve from the 8th to the 47th day after onset, during which considerable recovery had occurred. The initial and final curves are essentially normal.

ficial and open to much criticism. When 2 patients had the same muscle or group of muscles involved the patients whose muscles showed the lower grade in the muscle strength test was selected for treatment while the favored muscles of the other patient were selected as a control.

Testing procedures. As soon as the diagnosis of anterior poliomyelitis was made and prior to treatment the paralyzed or paretic muscles were given a manual strength test. The method used was that advocated by the National Foundation for Infantile Paralysis. The same physiotherapist always made successive examinations on the same patient.

In addition the muscles were tested for the reaction of degeneration. This test proved unsatisfactory, especially for children. The tests were difficult to duplicate even though made by the same examiner.

Electromyograms were recorded with a two-channel type A Olinier electroencephalograph equipped with ink writer. The patient was enclosed in a shielded room during the entire examination. The electrodes were of copper measuring 2.5 centimeters by 5 centimeters. They were coated with Cambridge electrode jelly and two of them were securely attached by means of Scotch tape to the skin over each muscle being examined. In each instance the affected muscle, its antagonist and the identical contralateral pair were examined. The examination was made as follows: (1) an active movement of one muscle recording from the active muscle and its antagonist; (2) repeating (1) but recording from the contra-

lateral pair; (3) active movement of antagonist and recording from active muscle and antagonist; (4) repeating (3) but with recording from identical pair; (5) this entire procedure was then repeated with the contralateral pair. A similar procedure but with passive motion was carried out. The range and duration of the passive movement was kept constant as possible for each muscle. In some instances the active movement was carried out against resistance.

Tensity frequency curves of the muscles selected for treatment were taken. A sine wave current was used in this test because the muscle response would always occur at the same point (peak) of the cycle. Frequency was plotted against current intensity (Fig. 1). The current intensity sufficient to produce a threshold contraction was recorded. This curve enabled us to select the frequency to be used for treatment.

Circumferential measurements were taken from a constant distance from a set anatomical landmark. Contralateral parts were used as a control for the late group.

All the tests were repeated every 3 months until discharge. In addition a subjective evaluation of the patient's progress was made.

Treatment. Once a patient was selected for electrical muscle stimulation the muscles were stimulated daily for 6 days a week. The generator used was a Variable Frequency Wave Generator built to yield a current form and range of frequencies which have been found (26) to be essential. With this generator it is possible to develop the maximum tension in the muscle with the minimum current intensity. The current delivered by it is sinusoidal in form (Fig. 2a). The frequency of the current can be varied from two to six thousand cycles per minute. It is possible to change gradually from one frequency to another while the patient is in the circuit. With frequencies from thirty to six thousand cycles per minute we find it more convenient to convert cycles per minute to cycles per second. Thus it is less cumbersome to speak of one-half to one hundred cycles per second. When the current reaches a frequency of two to one hundred cycles per second the current may be modulated or surged 100 per cent sinusoidally to

Fig. 2. a, Fundamental sinusoidal current 3 cycles per second. b, Modulating envelope of 3 seconds duration or

20 modulations per minute. c, Modulated sinusoidal current with carrier frequency of 3 per second

prevent a continuous tetanic contraction of the paretic muscle without relaxation (Fig. 2b). Modulation of the fundamental sine curve (Fig. 2c) prevents this and gives a graduated contraction similar to normal activity. The number of modulations per minute (Fig. 2b) determines the contraction rate of the muscles stimulated. This current we have termed a modulated sinusoidal current with a carrier frequency of two to one hundred cycles per second (Fig. 2c).

The frequency to be used for treatment was selected from the intensity frequency curve similar to that illustrated in Figure 1. The frequency requiring the lowest current intensity for a threshold contraction was selected. This initial frequency was used until later examinations showed the muscle responded maximally to a different frequency. When the frequency was two or more cycles per second this fundamental wave was modulated as previously explained. The modulation rate (the rate at which the muscles contracted and relaxed) was maintained consistently at a rate of twenty four times per minute throughout the entire course of treatment.

The complete technique of applying the electrodes to the muscles under stimulation will be dealt with in another communication. In some instances the unipolar technique was used while in others it was necessary to use a bipolar application. Patients differed a great deal and one could never predict with precision just where the point of maximum muscle irritability would be found. When possible the muscle was made to contract against resistance either by working against a weight or tying a foot for instance to the leg of the treatment table. Vigorous muscle contractions were secured. Each muscle or group of

muscles was stimulated daily. The muscles were stimulated for 10 minutes unless fatigue occurred. Contrary to clinical teaching there is no danger of stimulating to or beyond fatigue but it has been shown (20, 21) that it is a waste of time because unless tension is developed in the muscle treatment is useless. Stimulating a muscle four times with appropriate rest periods between stimulations has been found (21) to produce maximum results. However we stimulated the muscles only once daily.

The lower extremities of our patients appeared to have subnormal temperature therefore we found that a preliminary application of heat was desirable. We used a heat cradle of incandescent light bulbs for this purpose.

Since this study was concerned with human patients physiotherapy other than electrical stimulation was used. In the late group the physiotherapy they had received previously was continued. In the early group treatment consisting of heat, passive stretching and muscle re-education exercise was given three times weekly. Crutch walking was instituted as early as possible.

RESULTS IN THE LATE GROUP

The 13 patients in the group ranged in age from 2 years to 35 years. Four were females. The electrical stimulation was started from 6 months to 6 years after the acute onset of the disease. For example 1 patient 6 years after 2 at 2 years, 1 at 1 year, 1 at 9 months, 2 at 7 months and 4 at 6 months. The usual muscles were involved and need not be listed here.

In these 13 patients a total of 48 muscles were treated for from 4 to 18 months the average being 9 months and a total of 36 muscles were not treated.

Fig. 1 Intensity-frequency curves of right hamstrings, patient 7 showing the change in the shape of the curve from the 8th to the 47th day after onset, during which considerable recovery had occurred. The initial and final curves are essentially normal.

ficial and open to much criticism. When 2 patients had the same muscle or group of muscles involved the patients whose muscles showed the lower grade in the muscle strength test was selected for treatment while the favored muscles of the other patient were selected as a control.

Testing procedures. As soon as the diagnosis of anterior poliomyelitis was made and prior to treatment the paralyzed or paretic muscles were given a manual strength test. The method used was that advocated by the National Foundation for Infantile Paralysis. The same physiotherapist always made successive examinations on the same patient.

In addition the muscles were tested for the reaction of degeneration. This test proved unsatisfactory especially for children. The tests were difficult to duplicate even though made by the same examiner.

Electromyograms were recorded with a two-channel type A Offner electroencephalograph equipped with ink writer. The patient was enclosed in a shielded room during the entire examination. The electrodes were of copper measuring 2.5 centimeters by .5 centimeters. They were coated with Cambridge electrode jelly and two of them were securely attached by means of Scotch tape to the skin over each muscle being examined. In each instance the affected muscle, its antagonist and the identical contralateral pair were examined. The examination was made as follows: (1) an active movement of one muscle recording from the active muscle and its antagonist; (2) repeating (1) but recording from the contra-

lateral pair; (3) active movement of antagonist and recording from active muscle and antagonist; (4) repeating (3) but with recording from identical pair; (5) this entire procedure was then repeated with the contralateral pair. A similar procedure but with passive motion was carried out. The range and duration of the passive movement was kept constant as possible for each muscle. In some instances the active movement was carried out against resistance.

Intensity frequency curves of the muscles selected for treatment were taken. A sine wave current was used in this test because the muscle response would always occur at the same point (peak) of the cycle. Frequency was plotted against current intensity (Fig. 1). The current intensity sufficient to produce a threshold contraction was recorded. This curve enabled us to select the frequency to be used for treatment.

Circumferential measurements were taken from a constant distance from a set anatomical landmark. Contralateral parts were used as a control for the late group.

All the tests were repeated every 3 months until discharge. In addition a subjective evaluation of the patient's progress was made.

Treatment. Once a patient was selected for electrical muscle stimulation the muscles were stimulated daily for 6 days a week. The generator used was a Variable Frequency Wave Generator built to yield a current form and range of frequencies which have been found (26) to be essential. With this generator it is possible to develop the maximum tension in the muscle with the minimum current intensity. The current delivered by it is sinusoidal in form (Fig. 2a). The frequency of the current can be varied from two to six thousand cycles per minute. It is possible to change gradually from one frequency to another while the patient is in the circuit. With frequencies from thirty to six thousand cycles per minute we find it more convenient to convert cycles per minute to cycles per second. Thus, it is less cumbersome to speak of one-half to one hundred cycles per second. When the current reaches a frequency of two to one hundred cycles per second the current may be modulated or surged 100 per cent sinusoidally to

ing a large number with zero strength for treatment and selecting a large number with fair strength for no treatment. This was inadvisable from a statistical viewpoint which teaches that the controls and treated muscles should have been equally distributed between the various grades of strength. Though greater improvement occurred in the muscles electrically stimulated the difference and improvement is not statistically significant. Nevertheless the increase in strength is in the same direction as the increase in girth. When the increase in strength is correlated with the increase in girth a good degree of correlation is obtained (the correlation coefficient was $r = +0.69$).

General observations. Twelve of the thirteen patients manifested objective improvement relative to girth strength or both during the period of treatment of one or more of their paralyzed muscles as compared to nonstimulated muscles. Improvement however also occurred in nonstimulated muscles.

Four of the 13 patients whose muscles had been paralyzed for 7, 9, 10 and 25 months showed no improvement in voluntary motor function during the 12 to 18 months of observation according to the subjective judgment we formed by visually studying them. One patient showed neither objective nor subjective improvement after 5 months of treatment and was referred for operation to stabilize the ankle to counteract foot drop. The remaining 8 did manifest improvement in voluntary motor function and their stimulated muscles had been paralyzed in 3 for 6 months in 1 for 7 months in 1 for 11 months in 2 for 12 months in 1 for 21 months and in 1 for 6 years.

The following protocols indicate the type of subjective improvement observed by us.

Patient 2. Male 31 years of age electrical stimulation started 2 years after onset. At the initial examination the left knee joint was unstable and tired easily. After 5 months of treatment the knee joint was more stable and less easily fatigued.

Patient 4. Male 4 years of age electrical stimulation started 7 months after onset. At initial examination the left arm could not be abducted to side or front and elbow flexion was weak. After 1 year of treatment the arm was abducted side and front 10 times each, raised overhead 8 times without load and abducted 3 times with a 1 pound load. Forearm flexion definitely improved.

 $\frac{1}{59} = 6\frac{1}{2}\%$ improvement as group

Patient 6. Female 3 years of age electrical stimulation started 12 months after onset. At initial examination the patient could not sit up, could not balance with crutches and braces, could not crawl without brace and wore two long leg braces and crutches. After 10 months of treatment patient sits up well with good posture, wears one leg brace and crutches is less easily fatigued but balance is unimproved and knocks knees.

Patient 8. Female 10 years of age electrical stimulation started 6 years after onset. At initial examination patient wore 2 long braces and crutches could walk 25 feet twice daily with marked fatigue balanced alone with braces for 1 to 2 seconds with 2 braces was able to get out of wheelchair alone. After 9 months of treatment patient uses 1 long leg brace and 2 crutches, walks 300 feet twice daily with same fatigue as for 25 feet previously. Balances

The current used for stimulation or the range of electrical excitability of the muscles stimulated Eighteen of the muscles responded maximally to an unmodulated sinusoidal current ranging in frequency from 15 to 60 cycles per minute. Thirty of the muscles responded maximally to a modulated sinusoidal current with a carrier frequency varying from 5 to 15 cycles per second. The largest number 50 per cent responded to a modulated sinusoidal current with a carrier frequency of 5 cycles per second. Another 35 per cent showed a maximal contraction when stimulated at a frequency of 1 per second or less. Since the optimal frequency to produce a maximal contraction in normally innervated human muscles ranges from 15 to 100 cycles per second all but 4 of the muscles stimulated by us may be considered to be partially denervated. The more fibers denervated in a muscle the lower the frequency required to give a maximal contraction at minimal intensity.

Of the 48 muscles stimulated 30 showed no change in the frequency required to yield a maximal contraction during the course of treatment. In 2 the frequency decreased showing some further degeneration and in 16 the frequency increased indicating either a recovery in some of the motor neurones or a hypertrophy of the normally innervated muscle fibers.

Measurement of girth In 10 of the 13 patients it was possible to make reliable measurements of girth of either the leg, thigh or arm. The girth measurement constituted an attempt to quantitate what was detected with the eye in some cases or recorded with the camera. Whether the difference in the means between the initial and final average could be due to chance experimental error in making the measurements was determined by statistical methods.

Every final measurement made was greater than the initial measurement. The average of the initial measurement of 18 lower legs treated was 21.8 centimeters and the measurements at the end of the treatment was 23.2 centimeters. This difference of 1.4 centimeters is significant ($t=5.38$). The average initial measurement on the 14 thighs treated was 30.8 centimeters and the final measurement

was 32.7 centimeters. The difference of 1.9 centimeters is significant ($t=4.75$). The average initial measurement on the 13 arms measured was 19.2 centimeters and the final was 21.5 centimeters. The difference of 2.3 centimeters is significant ($t=8.8$).

The increase in girth was not due to an increase in subcutaneous fat. Nevertheless because 6 of the 10 patients were in various stages of growth (2 to 16 years of age) the possibility that growth was responsible had to be considered. Of the 6 patients, it is notable that 5 of them showed a greater increase in the girth of the treated extremity. The increase varied from 0.32 to 1.91 centimeters, the first figure being almost negligible but consistently observed. These patients had been afflicted 1 at 6 months, 2 at 7 months, 1 at 10 months, and 1 at 12 months prior to the start of electrical stimulation. Improvement then was observed although they had had complete motor paralysis for 6 months or longer.

The other 4 patients 19 years or over deserve some special reference. *Patient 8* a female aged 20 was afflicted in 1940, 6 years prior to reporting for this experimental study. This patient had received the best physiotherapeutic treatment available. Except for the right gastrocnemius which yielded a trace the muscles of both legs were completely paralyzed as regards voluntary contraction. Under treatment the girth of both thighs and both legs increased (stimulation 8 to 10 months). *Patient 11* a male aged 35 who was afflicted 21 months previously had the triceps of one arm treated for 13 months and the girth increased 3.49 centimeters. *Patient 13* female aged 27 was treated for paralysis of both legs which had been present for 6 months. The girth increases ranged from 2.86 to 4.76 centimeters. *Patient 12* a male aged 19 received treatment of the thigh and lower leg also 6 months after the onset of the disease. No increase in girth occurred but an improvement in strength was measured.

Measurement of strength The results obtained on the measurement of strength are shown in Table I. It is to be noted that 36 muscles were untreated and 48 were treated.

In selecting the muscles for treatment we decided to handicap the treatment by select

ing a large number with zero strength for treatment and selecting a large number with fair strength for no treatment. This was inadvisable from a statistical viewpoint which teaches that the controls and treated muscles should have been equally distributed between the various grades of strength. Though greater improvement occurred in the muscles electrically stimulated the difference and improvement is not statistically significant. Nevertheless the increase in strength is in the same direction as the increase in girth. When the increase in strength is correlated with the increase in girth a good degree of correlation is observed (the correlation coefficient was $r = +0.69$).

The girth increases ranged from 2.86 to 4.76 centimeters. *Patient 12* a male aged 19 received treatment of the thigh and lower leg also 6 months after the onset of the disease, no increase in girth occurred but an improvement in strength was measured.

Measurement of strength The results obtained on the measurement of strength are shown in Table I. It is to be noted that 36 muscles were untreated and 48 were treated.

In selecting the muscles for treatment we decided to handicap the treatment by select

alone with braces for 30 minutes and with one brace can get in and out of wheelchair alone.

Patient 10 Male, aged 2 years electrical stimulation was started 6 months after onset. At the initial examination one leg brace was worn activity was limited and child crawled and preferred to go without brace. One year later one leg brace was worn and activities of a normal three year old child were performed such as climbing and walking can not run and ride bicycle or scooter.

Patient 11 Male 35 years of age, who had been afflicted 21 months prior to the application of electrical stimulation. On first examination he was using 2 drop foot braces and 2 crutches and was exhausted after walking 50 feet with apparatus and had to rest for one hour before he could repeat. He was able to balance and stand alone with support for 1 or 2 minutes but could not go up or down stairs with or without aid and bend and touch the floor and straighten up again. He could extend the forearm against gravity with great effort.

After 10 months of treatment he could walk 125 feet with braces and crutch and could repeat every 5 minutes. He could ascend one flight of stairs by holding railing and bend over touch floor and straighten up. He was also able to extend forearm against a 1 pound weight five times. After 13 months he discarded the right ankle brace drives his car sit on chair without support.

Patient 12 Male aged 19 years electrical stimulation started 6 months after acute onset of disease. At the first examination he dragged right foot and was exhausted after walking 300 feet with crutches. He could ascend stairs with great effort but could not do a deep knee bend or bend to touch toes and return. He could not dance or play drums. After 11 months of treatment he walked any distance desired climbed stairs one at a time with ease, used streetcars dances and plays drums professionally drives a car and does not drag the right foot. Six months later he rode a bicycle and played a base drum with right foot for an entire evening.

Patient 13 Female 27 years of age electrical stimulation started 6 months after acute onset of disease. At the initial examination the patient after taking five steps with two crutches developed tremors in both arms and was able to stand with two crutches for 10 to 20 minutes. She was unable to get into or out of wheelchair and to dress herself. After 9 months of treatment the patient could walk 50 feet on crutches and 300 feet in walker. She could dress herself and get into and out of wheelchair or bed unaided and use left leg working foot pedal of sewing machine.

All these 8 patients though the muscles stimulated had been completely paralyzed for 6 months to 6 years showed real functional improvement during the period of treatment the least improvement being shown in the case of patient 8

RESULTS IN THE EARLY GROUP

During the 1946 epidemic a group of 7 patients were selected for treatment during the acute course (first 10 days) of the disease on the basis of the severity and extensiveness of the paralysis as determined by strength tests, electromyography, and clinical experience. A 'control group' of less afflicted patients was selected for observation. Both groups received the usual physiotherapeutic treatments. Electrical stimulation was started from 10 to 34 days after the acute onset of the disease and continued from 11 to 14 months.

Electrical excitability of muscles stimulated
The frequency required to yield a maximal contraction was followed. At the start of treatment of the 57 muscles stimulated 5 responded maximally to a frequency of 15 cycles per second 15 to a frequency of 10 cycles per second 22 to 5 cycles per second 1 to 3 cycles per second and 14 to 1 cycle per second. At the end of the treatment period 5 responded maximally to a frequency of 15 11 to 10 33 to 5 3 to 3 and 5 to 1 cycle per second.

Judging from the changes in the frequency required to produce a maximal contraction 21 remained the same 21 improved and 15 became worse.

Measurements of girth Of the 7 patients only 2 showed any decrease in the girth of the paralyzed extremities 1 of these patients lost 31 pounds during the period of therapy and the other 8 pounds.

When the girth measurements of the lower leg are averaged the initial was 28.2 centimeters and the final 29.3 centimeters ($t=2.68$) those of the thigh were initially 39.1 centimeters and finally 40.1 centimeters ($t=1.33$) those for the upper extremity initially 24.9 centimeters and finally 25.8 centimeters ($t=1.88$). Though these differences were not significant it is quite notable that the paralyzed extremities did not lose any girth but tended to gain. *In view of the fact that in the one year of therapeutic observation there was no significant change in body weight except in the 2 cases mentioned it is clear that the stimulation or treatment very definitely prevented atrophy.*

This prevention of atrophy is illustrated in the two photographs of flail legs shown in Figure 3.

b

Fig. 3. The amount of trophy 5 months after onset of the disease. a, Patient 8; b, patient 9. Both patients have flail lower extremities. Patient 8 showed no decrease in girth of thigh or leg during 4 months and lost 8 pounds of body weight.

Fig 4. Course of spasticity in patient 11. Upper record—right anterior tibial muscle. Lower record—right gastrocnemius muscle. In both records passive stretching of the right anterior tibial muscle has been performed. The horizontal line between arrows indicates duration of stretch. Record A taken May 14, 1946. Record B taken November 14, 1947.

due to overwork or constant fibrillation (29, 30) and that muscles atrophy from disuse and since Bowden and Gutman (1) have found that few if any muscle fibers in man have undergone complete degeneration to fibrous tissue in 3 years it is reasonable to believe that appropriate electrical stimulation will cause such muscle to contract and may cause some hypertrophy. It has been shown that denervated muscle can be caused to contract in a normal manner by the appropriate electrical stimulus and that the earlier the application of treatment (10, 11) and with the application of some load (5, 6, 16-21, 25) the more the atrophy and loss of strength is retarded. There is no reason why these facts should not apply to those fibers in a muscle which are degenerating slowly as a result of the destruction of the anterior horn cell that supplies them as well as to those which are atrophying due to disuse or absence of voluntary use. The negative results reported in the literature were obtained with inappropriate currents; this also applies to the excellent in-

vestigation of Chor and his associates which was done specifically to ascertain the value of currents used by clinicians at the time that work was done. The negative results were due to a failure to apply the physiological principle of the intensity frequency curve to the selection of the most appropriate electrical stimulus for a maximal or effective contraction.

To retard atrophy the treatment must be adequate. This means that (a) vigorous contractions with tension must be secured (b) the proper wave form of current is important (c) the treatment must be given daily and each muscle stimulated two or three times (d) and the muscle should be stimulated to the point of fatigue. To stimulate a fatigued muscle with the proper current is not injurious to the muscle; it is simply a waste of time since the muscle does not develop tension. As already stated it is agreed that to prevent atrophy a vigorous contraction with tension is required. To obtain a vigorous contraction with tension in an unanesthetized patient a current of low intensity must be used because the patient

Measurement of strength Fifty nine muscles were stimulated. Of these, 31 improved in strength, 22 remained the same and 6 became weaker (Table I)

As the strength tests were repeated it was quite evident at the second test that 10 to 14 days after the acute onset of the disease was too early to grade the full extent of the paralysis according to our observations, 1 month after the acute onset of the disease would be an approximate period for such appraisal

Since the muscles selected for treatment in the late and early groups were comparable in regard to the initial muscle grades of strength it is notable that the final grades are also comparable. This fact suggests that time is gained by starting treatment early

General observations All 7 patients regardless of the initial severity showed definite to marked improvement as would be expected. It is believed that the presentation of a protocol showing the improvement of each patient is unnecessary

THE RESULTS OF ELECTROMYOGRAMS AND RESPONSE TO STRETCH

Electromyograms were made on all the early patients and on all of the late patients who showed definite evidences of abnormality. Such evidences of abnormal innervation as prolonged stretch reflex spasticity and as activity on the heterolateral side on either active or passive movement were followed.

As has been reported by others, evidence of spasticity and abnormal reflex innervation was found in all the early cases. In our early cases it had disappeared or had markedly decreased at varying time intervals up to 7 months. In 1 of the patients who had not received electrical stimulation spasticity on stretch and heterolateral activity still persisted being increased over the early recordings, at 15 months.

Three of the patients in the late group showed a disturbance of reflex innervation. Patient 8 was particularly interesting because of the interval of 6 years between the acute attack of the disease and the start of electrical stimulation. In this case the prolonged stretch reflex or spasticity and heterolateral activity

disappeared during the period of treatment (10 months). Patient 11 who had been afflicted 21 months prior to the beginning of electrical stimulation manifested a very definite spasm in response to stretch as well as heterolateral activity this had almost completely disappeared after 2 months (Fig. 4). In patient 12 whose right leg had been paralyzed for only 6 months the evidence of abnormal reflex innervation disappeared after 12 months of therapy.

These observations are not recorded with the idea that electrical stimulation was specifically responsible, but to indicate how long evidence of abnormal reflex innervation may persist.

DISCUSSION

The observations made during this investigation have proved several points but leave the most practical points open for further investigation.

When this work was first contemplated we were told that one could not cause the atrophied muscles of the late cases of anterior poliomyelitis to contract by means of electrical stimulation and particularly the paralyzed muscle of the early case without causing intolerable pain. We have definitely demonstrated this view to be false. Such a view was based on a failure to comprehend the full significance of the physiological principle of the intensity frequency curve in electrical stimulation.

Our results on the early cases show that atrophy of the muscles can be markedly retarded even prevented for one year by adequate daily electrical stimulation of the muscle of the completely paralyzed or so called flail limb. Our measurements of girth also show that some hypertrophy was obtained in the paralyzed muscles of the late cases. This was slight on the average but nevertheless was an increase that could have occurred by chance or error in measurement in less than 1 out of 100 cases. We had anticipated these results because of our work and that of others on lower animals and because of our unpublished observations on human patients with peripheral nerve paralysis. Since it is clear that the atrophy of denervated muscle is not

plugged by a small tag of the otherwise normal and freely movable omentum. This plugging was so efficient that there was no leakage of pancreatic juice even in the 1 dog in which the pancreatic duct was distended behind the plug. It was obvious that the plugging by omentum was a form of self healing and that spilling of pancreatic juice into the peritoneal cavity was impossible after the omentum had become densely adherent to the region of the transected duct.

In contrast to these observations were the results in the other experiments of this series. With 1 exception, the dogs that had been fed before operation showed striking intraperitoneal changes at autopsy. The open duct was usually covered by omentum but this cover had not succeeded in completely sealing off the pancreatic duct and a large amount of fat necrosis and edema was frequently found under this cover as well as outside of it.

The dogs which had been starved before operation but given food shortly afterward though most of them ate only part of the food likewise showed marked changes. However the fat necroses were mostly localized in the pancreatic region and were not so extensive as in the dogs fed before operation.

The fact that intra abdominal fat necrosis was almost exclusively confined to the dogs which had been fed shortly before or after the operation suggested that increased postoperative flow of pancreatic juice caused by the secretin liberating effect of preoperatively or postoperatively ingested food played a decisive role. The observation that the intra peritoneal changes were much more extensive in the dogs fed before operation than in the ones fed afterward seemed to find its explanation in the fact that postoperative feeding could not be started before 8 to 10 hours after the operation after the effects of anesthesia had worn off and that the dogs took only part of the food thereafter.

To ascertain whether or not vagal stimulation of the pancreas has similar effects experiments were performed in which the dogs were starved before and after operation but were given vagotonic medication postoperatively. The dogs were sacrificed after only a short interval because we were interested mainly in

the observation of the immediate intra abdominal reaction. All the dogs had fat necroses in the pancreatic region and under the tag of omentum that covered the area of the transected duct. This shows that vagal stimulation of pancreatic secretion also though to a lesser degree than stimulation by secretin interferes with the healing mechanism which is regularly found in starved animals.

Transsection of the main pancreatic duct without subsequent ligation was tolerated so well by the starved dogs and followed by so remarkably few intra abdominal changes that we continued our experiments by studying the consequences of more extensive cutting of the pancreas. In the second series of experiments pancreatic duct and glandular tissue were cut wide open with results very similar to those in the first series of dogs.

The dogs starved before and after operation with only 1 exception showed merely insignificant intra abdominal findings at autopsy in spite of the extensive injury to the pancreas. The healing mechanism was the same as in the other experiments only the omentum was adherent to a wider area, and the pancreas was more indurated.

Most of the animals that had been fed before operation showed extensive fat necrosis in the peritoneal cavity.

Though the postoperatively fed animals of this series took water freely—probably due to the more extensive surgical procedure—they refused food after the operation or vomited shortly after eating so that no feeding effect could be expected. Therefore, dextrose was added to the drinking water postoperatively and the dogs drank considerable amounts of it. Very extensive intraperitoneal changes were found in these dogs similar to those in the dogs fed before operation.

It was evident in both series of experiments that in starved animals the peritoneum was protected from inflow of pancreatic juice by a most efficient sealing of the open pancreatic ducts. This was generally effected by omentum though colon or duodenum were involved occasionally. However the smooth healing in the starved dogs cannot be explained by the plugging process alone. An arrest or at least a pronounced decrease of pancreatic secretion

fluid in 1 dog a moderate number of generalized fat necroses in another animal localized fat necroses in the region of the pancreas and between the pancreas and the omentum in all 5 animals and some fat necroses in the pancreas in 1 dog

Series 2 Pancreatic Duct Slit Open

Group 1 Eleven dogs starved before and after operation. In 4 dogs, one branch of the main pancreatic duct was slit open and both branches in the remaining 7 dogs. Seven dogs were starved for 3 days after operation 2 for 5 days 1 for 7 days and 1 for 8 days. A few dogs appeared quite sick for the first few days but most of the animals showed remarkably little postoperative reaction. Two dogs died on the sixth day and 2 on the seventh day after the operation. Three of these dogs died of pneumonia and 1 of diffuse fat necrosis with a large amount of hemorrhagic intraperitoneal fluid. The other 6 animals were sacrificed between the eighth and twenty fifth postoperative day. All dogs except the 1 just mentioned showed only very few intra-abdominal changes. Only 4 had a small amount of bloody or pinkish exudate. One showed a few scattered fat necroses and 2 others showed a few fat necroses in the region of the pancreas. The area of the incised duct was covered in 1 dog by colon, and in the others by omentum. The firmness of the adhesion of omentum was in proportion to the time interval between operation and autopsy. The area of the incised duct was filled with a small clot in one dog and was slightly hemorrhagic in another. In 2 dogs, some purulent material was found between the incised duct and the cover of omentum. In 4 dogs the pancreas appeared normal while it showed various degrees of induration in the remaining animals. There were no obvious differences between the findings in the dogs which had only one branch and those that had both branches of the main duct incised.

Group 2 Eight dogs fed a few hours before operation but starved postoperatively for 2 to 8 days. One branch of the pancreatic duct was opened in the first 4 dogs, and both branches in the remaining 4. Some animals were very sick postoperatively and 3 died on the second third and fourth days respectively. Another

very sick dog was sacrificed the second day after operation. The other 4 dogs seemed to be in good condition and were sacrificed 8 and 9 days after operation. In 2 dogs, the appearance of well being was in contrast to the autopsy findings, which revealed most extensive intra-abdominal changes. In summary the findings in the 8 dogs of this group were bloody or pinkish intraperitoneal fluid in 5 most extensive localized and generalized fat necrosis in 3 less extensive localized and generalized fat necrosis in 3 and no fat necrosis at all in 2 dogs. The area of the incised duct was covered by omentum in all but 1 of the dogs. In 2 there was suppuration under the cover of omentum. The omentum was firmly adherent only in the dogs without fat necrosis. The pancreas was partly hemorrhagic in 3 dogs, showed edema and fat necrosis in 1 and various degrees of induration in 3. Whether one or both branches of the pancreatic duct had been incised did not seem to affect the results.

Group 3 Four dogs, starved preoperatively but given food and drinking water with dextrose shortly after operation. Both branches of the pancreatic duct were incised in the animals of this group. One dog died on the third another on the fourth postoperative day. The other 2 dogs were sacrificed on the third and fifth postoperative day respectively. All animals seemed sick in the postoperative period. The autopsy findings were various amounts of intraperitoneal fluid in 3 dogs extensive fat necrosis in 3 less extensive fat necrosis in the fourth. The area of the incised ducts was somewhat hemorrhagic in all 4 animals. It was covered by loosely attached omentum in 3 and by somewhat adherent omentum in the fourth. The pancreas was partly hemorrhagic in 1 dog but it appeared normal in the other 3.

DISCUSSION

The experiments of series 1 demonstrated that transecting the main pancreatic duct and leaving it open did not kill the animals within a short time and, under certain conditions was not followed by intraperitoneal pathologic changes. The dogs that had been starved before and after the operation showed a minimum of intra-abdominal changes at the autopsy. The cut duct, with 1 exception was

THE EXPECTANT TREATMENT OF PLACENTA PREVIA

A Study of 50 Maternal Deaths

CHARLES A GORDON M D F A C S., and ALEXANDER H ROSENTHAL, M D., F A C S
Brooklyn, New York

PLACENTA previa is an important cause of maternal mortality. Davis believes that at least half of the maternal deaths in the United States assigned to hemorrhage are due to placenta previa and estimates that 15 to 20 per cent of all our maternal deaths are due to this cause.

In Brooklyn where 1011 maternal deaths occurred in the ten year period 1937 to 1947 145 were assigned officially to hemorrhage. Upon study of case reports of all maternal deaths however hemorrhage was found to be the chief cause of death in 290 cases. Placenta previa was associated with death in 50 cases.

Placenta previa is still a major complication of pregnancy though wider use of cesarean section and blood transfusion particularly in the last decade has considerably reduced its mortality. Recent definite trend toward complete abandonment of dilating bags and version with stricter limitation of operative procedures to cesarean section and simple rupture of the membranes should result in minimal mortality in communities where obstetrical resources are adequate.

It has long been believed and taught that there is no place for expectancy in the management of placenta previa and that treatment should be initiated just as soon as the diagnosis has been made. The considerable fetal mortality has long been accepted as a natural corollary of early intervention. If there is little to support general belief that initial hemorrhage even though it may not be serious will be followed by others any one of which may be fatal expectant treatment should bring about substantial reduction in fetal mortality.

In 1945 Macafee (4) and Johnson independently yet almost at the same time stated that initial hemorrhage is rarely or never catastrophic, apart from vaginal manipulation and that recurrent hemorrhages do not lead to

fatal hemorrhage. They feel certain that expectant treatment is safe and proper provided certain precautions are taken. Macafee has reported 191 cases with but 1 maternal death (0.5 per cent) and a total infant mortality of 42 (22 per cent). Johnson reported 79 cases with 1 maternal death and a fetal mortality of 22.2 per cent. It is of interest to find that Davis has reported from the Chicago Lying In Hospital where expectant treatment has not been practiced 325 cases with but 2 maternal deaths (0.6 per cent) and a fetal mortality of 31.6 per cent. On the basis of these figures alone it would appear that the chief argument for expectant treatment is lowered fetal mortality.

Macafee (4) is willing to allow primigravidae but not multiparas to remain at home provided they live reasonably near the hospital and are warned not to permit any vaginal examination before admission. He knows of no case in which a severe spontaneous hemorrhage occurred in a primigravida. Numerous small hemorrhages cause him no anxiety. Curiously enough in only one of his cases was blood transfusion necessary.

Johnson will permit a patient with placenta previa to remain at home if hospitalization is impracticable for economic reasons having her return to the hospital for blood study after bleeding episodes of any consequence. He would be surprised to learn of a maternal death from placenta previa where nature has been allowed to take its course as regards labor and delivery. In fact he offers a reward for such a case. He states that the placenta should be allowed to separate naturally and that this is especially true if free bleeding is present.

Eastman believes that the recommendations of Macafee and Johnson will do much good provided they do not result in callous

must have occurred simultaneously with the plugging because otherwise marked intraductal accumulation of pancreatic secretions would have resulted, with subsequent distention of the duct system however dilatation of the pancreatic ducts was found in only 1 dog.

Stimulation of the pancreas by liberation of secretin due to preoperative or postoperative feedings and similarly by vagal stimulation obviously counteracts the arrest of pancreatic secretion which occurred in the starved animals. Consequently when the intraductal secretory pressure of the pancreas exceeds the adhesive power of the omental plug leakage of pancreatic juice takes place and causes intraperitoneal fat necrosis. However after a certain time the gland no longer seems to respond to normal alimentary stimuli. This is similar to the findings in dogs with ligated pancreatic ducts and is confirmed by the results of serum amylase tests which showed an initial postoperative rise with return to normal after a few days, just as is the case after ligation of the duct. Autopsy revealed induration of the pancreas in a number of dogs of both series. This is the consequence of the sealing off of the pancreatic duct and as is known from experimental ligation is the forerunner of more or less complete atrophy of the glandular tissue, which eventually must take place if the pancreatic duct is occluded.

SUMMARY AND CONCLUSIONS

Transsecting the pancreatic duct or slitting it wide open as a rule does not cause intraperitoneal fat necrosis if the animal has been starved before and after operation. Following the operation omentum attaches itself to the wound of the pancreas and plugs the open duct. At the same time an arrest of pancreatic secretion seems to occur. After a few days the omental plug is firmly adherent to the pancreas and the healing process is terminated as far as the prevention of leakage of pancreatic juice is concerned. However the sealing off of the pancreatic duct, similar to closure of the duct by ligature eventually is bound to lead to fibrosis and atrophy of the glandular tissue.

Preoperative or postoperative feeding of the animals is usually followed by extensive intra-

abdominal fat necrosis while postoperative vagotonic medication leads to similar but less extensive changes. Obviously feeding is a more potent stimulus for pancreatic secretion than a few injections of pilocarpine or prostigmine. It is concluded that increased flow of pancreatic secretions due to secretin as well as to vagal stimulation offsets the protective plugging process. This allows pancreatic juice to enter the peritoneal cavity and to cause fat necrosis.

From these animal experiments conclusions can be drawn which may be of importance in the treatment of surgical or accidental wounds of the pancreas and in surgery of the pancreas in general. The following measures are suggested for clinical trial.

1 If a pancreatic duct is transected and if implantation into the intestinal tract is not feasible it may be best to attach omentum to the ligated stump since omentum seems to be capable of sealing off the duct even if the ligature should fail.

2 In the case of injuries to the glandular tissue of the pancreas, it may be advisable to attach omentum to the pancreas even if the lesion of the pancreas has been sutured. This may help to reduce the incidence of postoperative pancreatic fistulas.

3 In cases of elective surgery on the pancreas, or when the gland may be injured in the surgical procedure it seems advisable to prolong the routine period of preoperative starvation and to give preoperative medication which does not stimulate pancreatic secretion but which depresses it.

4 After operation on and injuries to the pancreas it seems advisable to keep the external pancreatic secretion at a minimum for several days by inhibiting it through medication and by avoiding humoral as well as vagal stimulation of the pancreas.

Although these statements are based on controlled animal experiments, clinical observations will have to show to what extent they are applicable to clinical surgery.

THE EXPECTANT TREATMENT OF PLACENTA PREVIA

A Study of 50 Maternal Deaths

CHARLES A GORDON M.D., F.A.C.S., and ALEXANDER H ROSENTHAL, M.D. F.A.C.S.,
Brooklyn, New York

PLACENTA previa is an important cause of maternal mortality. Davis believes that at least half of the maternal deaths in the United States assigned to hemorrhage are due to placenta previa and estimates that 15 to 20 per cent of all our maternal deaths are due to this cause.

In Brooklyn where 1011 maternal deaths occurred in the ten year period 1937 to 1947 145 were assigned officially to hemorrhage. Upon study of case reports of all maternal deaths however hemorrhage was found to be the chief cause of death in 290 cases. Placenta previa was associated with death in 50 cases.

Placenta previa is still a major complication of pregnancy though wider use of cesarean section and blood transfusion particularly in the last decade has considerably reduced its mortality. Recent definite trend toward complete abandonment of dilating bags and version with stricter limitation of operative procedures to cesarean section and simple rupture of the membranes should result in minimal mortality in communities where obstetrical resources are adequate.

It has long been believed and taught that there is no place for expectancy in the management of placenta previa and that treatment should be initiated just as soon as the diagnosis has been made. The considerable fetal mortality has long been accepted as a natural corollary of early intervention. If there is little to support general belief that initial hemorrhage even though it may not be serious will be followed by others any one of which may be fatal expectant treatment should bring about substantial reduction in fetal mortality.

In 1945 Macafee (4) and Johnson independently yet almost at the same time stated that initial hemorrhage is rarely or never catastrophic apart from vaginal manipulation and that recurrent hemorrhages do not lead to

fatal hemorrhage. They feel certain that expectant treatment is safe and proper provided certain precautions are taken. Macafee has reported 191 cases with but 1 maternal death (0.5 per cent) and a total infant mortality of 42 (22 per cent). Johnson reported 79 cases with 1 maternal death and a fetal mortality of 22.2 per cent. It is of interest to find that Davis has reported from the Chicago Lying In Hospital where expectant treatment has not been practiced 325 cases with but 2 maternal deaths (0.6 per cent) and a fetal mortality of 31.6 per cent. On the basis of these figures alone it would appear that the chief argument for expectant treatment is lowered fetal mortality.

Macafee (4) is willing to allow primigravidae but not multiparas to remain at home provided they live reasonably near the hospital and are warned not to permit any vaginal examination before admission. He knows of no case in which a severe spontaneous hemorrhage occurred in a primigravida. Numerous small hemorrhages cause him no anxiety. Curiously enough in only one of his cases was blood transfusion necessary.

Johnson will permit a patient with placenta previa to remain at home if hospitalization is impracticable for economic reasons having her return to the hospital for blood study after bleeding episodes of any consequence. He would be surprised to learn of a maternal death from placenta previa where nature has been allowed to take its course as regards labor and delivery. In fact he offers a reward for such a case. He states that the placenta should be allowed to separate naturally and that "this is especially true if free bleeding is present."

Eastman believes that the recommendations of Macafee and Johnson will do much good provided they do not result in callous-

ness to hemorrhage. With this we agree yet their importance warrants careful consideration. The expectant treatment advocated by both authors is based upon their experience and belief that hemorrhage, whether initial bleeding or subsequent and no matter how often repeated will not cause death in the absence of vaginal examination or manipulation.

Since we believe that the risk of this method of treatment may best be measured by careful review of the sequence of events which have preceded death in a considerable number of cases, we have studied 50 case reports of maternal deaths associated with placenta previa.

MATERIAL FOR STUDY

All 50 deaths occurred in Brooklyn in hospitals of various types. There were 10 primigravidas and 39 multigravidas. In 1 case parity is unknown. 58 were white women and 2 were negroes. The duration of pregnancy was 6 to 8 months in 13 cases, 8 months to term in 14 cases and 21 women were at term in 2 cases; the duration of pregnancy was not stated.

Cesarean section had been performed in 22 cases. Delivery from below had occurred in 25 cases. 3 women died undelivered. In 5 cases the first hemorrhage occurred after the onset of labor. The causes of death appear in Table I.

Placenta previa was complete in 25 cases, partial in 9 cases and marginal in 12 cases; not stated in 4 cases.

Hemorrhage followed several patterns with considerable variation in the time of onset

amount of initial hemorrhage, and the time and character of recurrent bleedings. It may be summarized as follows:

1 Initial profuse antepartum hemorrhage, 12 cases.

2 Spotting for 4 or 5 weeks followed by moderate or profuse hemorrhage, 3 cases.

3 Recurrent slight bleedings for 1 to 4 weeks followed by moderate or profuse hemorrhage, 15 cases.

4 Recurrent slight bleedings for 4 weeks to 4 months followed by moderate or profuse hemorrhage, 7 cases.

5 Initial moderate bleeding followed within 1 to 6 weeks by a second moderate or profuse hemorrhage, 7 cases.

6 One episode of bleeding in the 7th month, 1 case.

7 First hemorrhage intrapartum, 5 cases.

It is not practicable to discuss the general condition of each patient before treatment was instituted or to describe hemorrhage in terms other than slight, moderate, profuse and severe as in the case reports of death. As a result of hemorrhage, however, 13 women were in poor condition before active treatment, 7 were in shock, 5 actually in labor (Table II). In primigravidas antepartum hemorrhage was not severe in any case except after rectal examination (2 cases). In 1 case in which severe hemorrhage occurred early in labor, brief clinical data are of interest.

CASE 1. In a patient of 35 years, severe hemorrhage occurred a few hours after the onset of labor in the 38th week of pregnancy. She was admitted to the hospital in shock, with a pulse rate of 140. Plasma and 500 cubic centimeters of glucose solution were administered and cesarean section was performed. Hemorrhage continued postpartum, and the uterus and vagina were packed. Death occurred 9 hours later.

In multiparas hemorrhage was more severe. Of the 7 women admitted to the hospital in shock, 6 were multiparas, 4 were in labor. The significant clinical data of the only 2 cases in which severe antepartum hemorrhage occurred follow:

CASE 2. A secundigravida aged 34 years at term was admitted to the hospital with pain in the chest, dyspnea and cyanosis. There was no vaginal bleeding yet she had bled in the 34th week. Rectal examination was followed by profuse hemorrhage. Death 1 hour later with baby undelivered was attributed to pulmonary embolism. At autopsy the lung condition was not significant. Complete placenta previa was present.

CASE 3. A secundigravida aged 29 years suffered severe initial hemorrhage 2 hours before the onset of labor in the 38th week of pregnancy. It was estimated that 2000 cubic centimeters of blood were lost in 4 hours before patient was admitted to the hospital in shock, with blood pressure 70/50 and pulse rate 150. Plasma (500 c.c.) and blood (500 c.c.) were administered. Six hours later after loss of fetal heart sounds, patient was examined vaginally and complete placenta previa was felt through a cervix which was dilated 4 centimeters. The cervix was then dilated manually and a No. 4 Voorhees bag was introduced. The patient complained of intense abdominal pain the uterus became boardlike and shock deepened. The bag was then removed and blood (500 c.c.) and plasma (500 c.c.) were again administered. The cervix was then dilated again manually and version and extraction of a stillborn fetus were performed through the placenta which was then removed manually. Death on the 9th day postpartum was due to embolism proved by autopsy.

MANAGEMENT

In no case was there record of a pelvic examination prior to hospitalization. In 4 cases rectal examination precipitated profuse hemorrhage and in several other cases repeated rectal examination did not. Not infrequently a patient was discharged from the hospital after vaginal examination failed to reveal placenta previa only to return later after another hemorrhage at home upon re-examination the diagnosis was clear. In most cases blood was transfused at some time before death yet the amounts were usually inadequate or transfusion was performed too late. The initial management is summarized in Table III.

In every case but 1 (eclampsia) hemorrhage contributed to death yet infection was the immediate cause of death in 19 cases, 15 of them after abdominal delivery.

TABLE III—INITIAL MANAGEMENT

Procedure	No. of cases
Cesarean section	22
Internal version	4
Version and extraction	8
Braxton-Hicks version	4
Rupture of membranes	3
Bag alone	3
Pinnard maneuver	1
Vaginal pack	1
Incision of cervix and forceps	1
Undelivered spinal anesthesia	1
Undelivered eclampsia	1
Undelivered, no treatment	1
Total	50

Postpartum hemorrhage and shock caused death in 23 cases, 3 after cesarean section and 20 following delivery from below. Extraction followed version in 8 cases, in 1 case after Braxton-Hicks version. A Voorhees bag preceded version in 6 of these cases. In a patient with a marginal placenta previa the breech was extracted through a cervix dilated but 3 centimeters. In another case delivery was effected by forceps after lateral incisions in a cervix dilated less than 3 centimeters. And a patient treated by vaginal tamponade died of postpartum hemorrhage after precipitate delivery of twins. In another case rupture of the uterus followed the Pinnard maneuver.

Severe postpartum hemorrhage occurred in all of these cases. Rupture of the uterus is known to have occurred in 2 cases while in another a deep cervical laceration was reported. In 5 additional cases all after version, though a tear in the uterine wall was not actually palpated, it is our belief that clinical evidence will support the diagnosis of ruptured uterus. With the exception of a death from severe infection 34 hours after version and extraction all 23 patients died within a few hours of delivery.

Fetal survival in the cesarean section group was 14 and in the pelvic delivery group 4.

DISCUSSION

In the management of placenta previa the prime indication is prevention of death from hemorrhage. Infection may not be controlled as well as hemorrhage proper management of hemorrhage is a clear prerequisite of treatment. Death from infection occurs more commonly after cesarean section, yet many wom-

ONE STAGE RESECTION AND ANASTOMOSIS OF THE COLON

A REVIEW of surgical literature of the past 5 years discloses a decided trend toward a return to primary resection and anastomosis of the colon. McKittick in 1948 comprehensive consideration of surgery of the colon wrote that "It shares with all other surgical procedures the improvement in results following the many advances in the care of patients that have occurred in recent years, tending I believe more nearly to standardize surgical treatment of cancer of the colon than has been possible before." The writer as a result of a survey by questionnaire undertaken in 1947 to determine current trends in the surgical treatment of carcinoma of the large intestine as practiced by surgeons with relatively large and proved experience in this field has reached the same conclusion. Thirty-six or 72 per cent indicated that in at least 50 per cent of cases they elected primary resection and

anastomosis as the procedure of choice. One stated that he never employs this maneuver while four claimed one hundred per cent performance. Between these extremes the varied incidence of performance was as follows: 5 to 24 per cent of cases 7 surgeons, or 14 per cent 25 to 74 per cent 11 surgeons, or 22 per cent and 75 to 100 per cent of cases, 31 surgeons or 62 per cent. Notwithstanding this popular preference for a one stage operation it appears significant that 6 of the 10 surgeons in our survey who are generally conceded to be pre-eminent in this field and whose replies were tabulated separately estimated that they performed primary resection and anastomosis in not more than 25 per cent of instances. One of these T. E. Jones, has not anastomosed the distal colon primarily since January 1938. During a period when most of the surgeons in the majority group who now favor primary anastomosis performed exteriorization procedures exclusively he was one of the principal advocates of immediate anastomosis which he accomplished with the relatively low mortality (for that period) of 14 per cent in 128 cases. Dissatisfied, however with this rate he adopted the exteriorization technique of Rankin (obstructive resection) and in a series of 117 cases performed without the benefit of chemotherapy reported a mortality of only 5 per cent. Moreover the overall hospitalization period averaged only 26 days, including the period for closure of the temporary colostomy. David employs an exteriorization operation in all but 5 to 10 per cent of cases and the Lahey Clinic in all but 10 to 15 per cent of such lesions. Rankin, Cole MacFee and Dixon perform primary

anastomosis in not more than 35 per cent of instances

Although a considerable majority of those interested in surgery of the large intestine are in agreement as to the operation of choice in lesions of the distal colon a decided difference of opinion prevails as to which factor or factors chiefly are responsible for the current relatively low mortality which accompanies resection and immediate anastomosis. A few notably Dixon Heyd and White believe that routine establishment of complementary proximal drainage favorably influences mortality whereas a majority (85 per cent) in the survey conducted by the writer especially Stone Waugh Meyers Wangenstein and Campbell have taken positive stands to the effect that such decompression as a routine measure is not essential to a low mortality in primary anastomosis. The Miller Abbott tube was considered a valuable adjunct to resection of the distal colon by only five whereas special merit was ascribed to the Devine colostomy by only three.

Controversy also continues concerning the comparative efficacy of the closed and open methods of intestinal anastomosis. Whipple Meyers and a few others have strenuously criticized the aseptic technique particularly those which employ a special clamp. On the other hand Stone Rankin Wangenstein Waugh White Pemberton Dixon, and McKittick are among the majority (60 per cent in our survey) who believe mortality is favorably influenced by the closed technique. A similar division of opinion is found in the evaluation of chemotherapy and the antibiotics. Jones Stone Lahey Cattell Collier Wangenstein Gurd McKittick and a few others use them not at all or only rarely. However most surgeons (84 per cent in our survey) consider these agents important ad-

juvants in primary anastomosis of the colon and utilize them routinely. The extremes are represented on the one hand by Jones who never employs chemotherapy in any form and on the other by Pemberton who feels that the part played by chemotherapy in the reduction of mortality in surgery of the colon is 'as spectacular and revolutionary as the changes wrought by iodine therapy in surgery of exophthalmic goiter. Actually there have not been reported sufficiently large series of cases to permit accurate evaluation of the favorable influences of any one therapeutic agent or technical maneuver. More likely, as recently emphasized by Allen, Ravdin, McKittick and others a combination of factors have contributed to the improved results as (1) a better understanding and utilization of preoperative preparation especially as regards anemia and serum protein deficiency, (2) improvement in anesthetic methods and (3) the advent of chemotherapeutic agents for oral use during the preoperative period.

It is also difficult properly to determine the relative merits of obstructive resection and primary resection and anastomosis in the treatment of cancer of the colon prior to the publication of large series of cases in which are included such revealing data as operability, mortality and five year survivals. The fallacy of attaching significance to statistical consideration of a limited number of cases such as have been recently reported has been demonstrated frequently. Initial series of cases usually consist of carefully selected patients and as a consequence mortality is lowest for the first score or so of operations.

MacFee long an advocate of primary anastomosis as the procedure of choice recently aptly expressed the concern with which a number of us have viewed the all-or-none

attitude adopted by many surgeons in regard to primary suture of the distal colon after resection. He says "When primary resection is intended and an unforeseen complication is encountered there is always the inclination to proceed with the definitive operation as planned bearing in mind but at the same time disregarding the fact that conditions for the operation are not ideal. The results may be chastening to the surgeon and irreparably bad for the patients. It is the middle ground cases that offer the greatest temptation and therefore the greatest danger."

A. STEPHENS GRAHAM.

PANCREATIC PHYSIOLOGY IN THE LIGHT OF RECENT SURGICAL EXPERIENCES

THE surgery of pancreatic neoplasms as developed in recent years has afforded considerable opportunity for the study of pancreatic physiology. Previously much that was taught concerning the pancreas was based upon observations made in the laboratory upon various types of animals; the inference was that the facts thus gleaned in all probability applied to human beings. Recent surgical experiences however would indicate that human pancreatic physiology differs in certain respects from that observed in the several varieties of laboratory animals.

In a recent publication¹ dealing with the etiology of acute pancreatitis as observed in cats and produced by ligation of the main ducts and stimulation of the gland by feeding it is concluded that the most important factor is obstruction of the ducts. Neoplasms of the head of the pancreas or ampulla produce high grade obstruction of the ducts and these patients rarely exhibit concomitant acute

pancreatitis, although prior to operation the obstruction did exist and there was stimulation when the patients ingested food. Further more pancreatoduodenectomy without implantation of the transected neck into the jejunum is in effect a ligation experiment in man and the operation is not followed by acute pancreatitis when the patient recovers; the fistula is closed and the gland is stimulated by ingestion of food.

In the earlier phases of the development of pancreatic surgery the question was frequently asked by internists, physiologists, and others why the patients did not develop acute pancreatitis. Why they should be expected to do so is not clear but prior teaching certainly gave a widespread impression that there would be great hazard in surgical manipulation of the pancreas. It would appear that this complication is so unusual that no surgeon now hesitates to attack the pancreas for fear of acute pancreatitis.

In the experience of the writer operative trauma to the dog's pancreas is very well tolerated indeed, and attempts, by mashing the gland *in situ* to produce the homologues of the large posttraumatic pseudocysts in these animals that are observed in man following crushing trauma to the upper abdomen have been negative.

Another interesting observation in man has been the variation in character of the stool following complete occlusion of the external secretion as a result of pancreatoduodenectomy without reimplantation of the transected neck of the gland. The stools are fatty bulky and relatively frequent in some of the patients but by no means all of them. In one case there was steatorrhea and after operation where only the bile was returned to the alimentary tract the stools were normal. In another instance normal nutrition has been maintained for two years, in another for

¹Liss, R., and Maddock, Stephen, *Surgery* 1942, 24, 902.

four years in a third for five and a half years² in still another patient eight years,³ where the pancreatic juice has been completely occluded. A ready explanation is that accessory pancreases must exist to afford the external secretions but in the absence of final proof of this, other theories such as the presence of secretions from other parts of the bowel that sometimes can substitute for pancreatic juice, are just as valid and possibly more thought provoking.

²Brunschwig, A. *Lyon chir.* (In Press).

³Whipple, A. O. Personal communication.

The patients who have received total pancreatectomy afford excellent opportunities for study of carbohydrate metabolism in general. An example is the arresting observations that the totally depancreatized human requires relatively modest doses of insulin, less than in many of those who are spontaneously diabetic with the entire pancreas *in situ*. Furthermore total pancreatectomy in the diabetic subject does not result in appreciable increase in the severity of diabetes. These facts suggest new avenues for further study of diabetes mellitus in man.

ALEXANDER BRUNSCHWIG

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE Swedish School of Radiology developed under the beneficent direction of the universally beloved Gosta Forssell has grown into one of the best radiological centers in the world, one which has contributed in a very large manner to the advancement of medicine in general and of radiology in particular. The new discoveries and techniques in radiology emanating from this school have been published in the various radiological journals, particularly in the *Acta radiologica* and the supplementary volumes of the *Acta* which have now reached more than sixty five in number.

The present series of lectures, *Roentgen Studies of the Lungs and Heart*¹ by Nils Westermark, M.D., delivered at the Center of Continuation Studies of the University of Minnesota at the instigation of Professor Leo G. Rigler, integrates anatomy physiology pathology and clinical medicine in the application and interpretation of roentgen diagnostic procedures most useful in the study of the heart and lungs. This is a valuable collection of dissertations very much worth study at the hands of internists pathologists, cardiologists, and radiologists.

JAMES T. CASE.

THE book *General Endocrinology*² by Turner was written primarily for students who are concentrating on experimental biology rather than for the practicing physician or medical specialist. The discussion of each gland includes comparable structures in lower vertebrates and invertebrates which greatly add to the value of the book. There is sufficient gross and microscopic anatomy to permit review of the important aspects of the glands. The review of developmental and comparative anatomy certainly adds to the interest and understanding. The biochemistry of each hormone and its physiological effects are well treated and finally the results of over or under secretion are touched upon. The interrelationship of the several endocrine glands has been sufficiently stressed. Perhaps one of the book's best features is the generous reference to the classical experiments which have been done in the various fields.

The bibliography at the end of each chapter is excellent as it contains all the important references on the subject.

ROENTGEN STUDIES OF THE LUNGS AND HEART. SERIES OF LECTURES DELIVERED AT THE CENTER FOR CONTINUATION STUDY, UNIVERSITY OF MINNESOTA. By Nils Westermark, M.D. Edited by Leo G. Rigler, M.D. Minneapolis: The University of Minnesota Press, 1944.

GENERAL ENDOCRINOLOGY. By C. Donald Turner, Ph.D. Philadelphia and London: W. B. Saunders Co., 1944.

While this book was prepared chiefly for the student general medical practitioners and specialists in endocrinology will find it interesting and helpful. It is well organized and well presented and is recommended to all interested in medicine and its allied fields.

BROOK BAKER.

THE present edition of *Recent Advances in Surgery*³ by Harold C. Edwards is the third edition of a series formerly edited by Sir Henage Ogilvie, the last published in 1929. A volume of 495 pages, well printed with numerous illustrations, it will be found of great interest to the general surgeon.

There are seven parts. The first deals with the general problems of wound healing shock, burns, fluid balance and antibacterial therapy. The second is particularly well done, on the alimentary system. There are notably good sections on the esophagus and on the rectum. The third part by R. C. Brock covers the thorax. The fourth by D. W. C. Northfield reviews the nervous system with a section on head injuries and another worth noting on intracranial aneurysms. The fifth is concerned with blood vessels and anticoagulants. The sixth summarizes the advances in the ductless glands, including prostate and breast. There is an illustrated description of Millin's operation for prostatic hypertrophy. The seventh and last part by Sir Stanford Cade is an excellent review of radiotherapy in malignant disease.

There is so much material that one may wonder how it is compressed. For example in the section on the thorax after a short introduction, the surgery of the heart is described, including wounds, foreign bodies suppurative pericarditis, constrictive pericarditis, mediastino-pericarditis, congenital abnormalities, pulmonary atresia, angina pectoris, extra-coronary and intercoronary communications. A detailed chapter follows on bronchial carcinoma. And, at the end of each chapter an adequate list of references will be found. An index also follows at the end of the book.

This book is very readable and it can be recommended to those who would review these fields. It differs from our Year Book in that it covers a longer period and a smaller field. Referring to it one can be assured of a summary of the advances in each field and a list of important references.

JOHN L. ATLEE, JR.

RECENT ADVANCES IN SURGERY. By Harold C. Edwards, Ch.B.E., M.S. F.R.C.S. 3rd ed. Philadelphia: The Baltimore Co. 1944.

TO those interested in the preparation and publication of scientific papers *Medical Writing*¹ by Morris Fishbein, Editor and Jewel F. Whelan, assistant to the Editor of the *Journal of the American Medical Association* will be found most useful. The book contains a wealth of valuable information and the very full index makes this information easily accessible. One might wonder why pains were taken to spell out the captions to Figure 12 B in the chapter on Illustrations. In letters so black and ungainly as to focus attention on them rather than on the drawing itself. Some of the rules given for the copy editing of manuscripts for American Medical Association publications might be considered arbitrary but the publications of the Association speak for themselves as to the high quality of the work the Association does. *Medical Writing* should be of great help to the doctor preparing a manuscript, to his secretary who copies it and to the copy editor whether or not associated with the American Medical Association.

M. E. SPENCER.

THE volume by Dr R. B. H. Gradwohl *Clinical Laboratory Methods and Diagnosis*² has increased in size with every edition until now in the fourth edition it fills three large volumes and more than 3,300 pages. It is encyclopedic in scope and modern in content. In addition to the chapters which describe all the tests which are performed in the ordinary day's work of a large hospital laboratory there are also comprehensive sections on electrocardiography, autopsy technique, toxicological methods and the detection of crime by laboratory methods. The entire third volume which is written in collaboration with Dr Pedro Fouri of the Faculty of Medicine of Havana University is devoted to parasitology and tropical medicine and is noteworthy for the pictures illustrating the pathology of the various diseases.

The general plan of the book includes a detailed description of nearly all the modifications of the different laboratory procedures, which is followed by a discussion of the interpretation of the results. Frequent lengthy accounts of certain clinical and therapeutic aspects of the diseases under discussion are also included. A commendable feature is the detailed description of the various scientific instruments which are used in the laboratory. Each manufacturer's instrument, although frequently designed on the same basic physical or chemical principles, often requires minor but essential variations of operation and it is helpful to have these differences explained.

There is a good discussion of the cytological diagnosis of cancer of the uterus, bronchus and prostate by the methods of Papanicolaou, of Ayre and Dakin and of others followed by an even better evaluation

of the results of this method of diagnosis. The illustrations for this section of the book are especially fine and for the most part are reproduced from articles which appeared in *SURGERY GYNECOLOGY AND OBSTETRICS*.

This book will undoubtedly be used constantly as a guide in many laboratories and should prove a ready aid to the experienced as well as the inexperienced laboratory worker. This reviewer however would like to suggest that future editions could be considerably shortened by critical editing of the material which is included in the book and the use of an economical literary style. Much chaff could be winnowed from the wheat.

WILLIAM B. WARTMAN.

THE sixth edition of *Recent Advances in Anesthesia and Analgesia*³ by C. Langton Hewer was designed to present information regarding recent developments in anesthesiology. The small concise volume deals briefly with basic principles and new topics. Prominence is given to the use of curare and similar drugs as specific muscle relaxants. Numerous references are listed at the end of chapters and many illustrations of equipment are included.

Of particular interest are the chapters which take up psychological aspects and theoretical considerations of anesthesiology. Special attention is given to charts and records with emphasis on the card index systems. The discussion of trilete is of value as this nonflammable agent is little known in this country. The use of anesthesia in domiciliary practice is a field in which most American anesthetists lack experience. The author had extensive wartime work with cases of trauma, and his remarks regarding the administration of anesthesia to patients in shock are well worth while.

Considerable space has been devoted to mention of experimental infrequently used and obsolete drugs. The discussion of shock therapy quickly dismisses blood transfusion but provides a conspicuous list of analeptics. The use of ethyl chloride analgesia for short dental operations seems a hazardous procedure due to the cardiac effects of this potent drug. It is stated that nitrous oxide anesthesia is used extensively in the United States for major surgery; this secondary saturation technique has been discarded by most because of the anoxia involved.

The text is general in treatment and no technical details are given for the most part. The subject matter includes such fundamental topics as premedication agents and methods of anesthesia apparatus, explosion hazards, oxygen therapy and anesthetic management of various types of surgical cases. The student will find the basic principles of anesthesiology briefly outlined. The specialist will note some points unfamiliar to American practitioners. However, the primary interest of this book is its presentation of the British viewpoint in the practice of anesthesiology.

³RECENT ADVANCES IN ANAESTHESIA AND ANALGESIA. By C. Langton Hewer. 6th ed. Philadelphia and Toronto: The Blakiston Co., 1948.

MARY FRANCES POE.

¹MEDICAL WRITING, THE TECHNIQUE AND THE ART. By Morris Fishbein, M.D. and ed. Philadelphia and Toronto: The Blakiston Co., 1948.

²CLINICAL LABORATORY METHODS AND DIAGNOSIS: A TEXT BOOK OF LABORATORY PROCEDURES WITH THEIR INTERPRETATION. By R. B. H. Gradwohl, M.D., D.Sc., F.R.S.T.M. & H. (Lond.). Volumes 1-3. 4th ed. St. Louis: The C. V. Mosby Co., 1948.

AN amplification of the author's earlier book *A Diseases of the Ear, Nose and Throat* by William Wallace Morrison includes the same type of anatomic and histopathologic line drawings which clarified that excellent text.

This is no exhaustive rebash of abandoned theories. It presents up to date findings and is documented with references to recent work at the end of each chapter. Valuable diagrams of endaural surgical procedures, including fenestration, excellent discussions of nasal allergy and of headaches and of tracheo-bronchial neoplasms, have been added. There is an extensive formulary of medicaments for patients, and a valuable symptom index.

As a guide for the general practitioner and a ready reference work for the specialist in this field Morrison's book cannot be surpassed.

RALPH A. FENTON

IN the third edition of *Essentials of Pathology*, A. Smith and Gault have maintained the standard of the two previous editions and have made a number of changes which are worthy of mention. The photomicrographs are clearer, more numerous, and are selected to demonstrate the more common lesions. A similar comment may be made about the photographs of gross specimens and the roentgenograms. It is suggested that the colored plates on malarial parasites, the various cells of the hematopoietic system, and the eye grounds could be supplanted by colored plates of true pathologic changes. The former ones are ordinarily seen in manuals of clinical medicine.

Discussion still continues on the use of the case method of teaching. Since it remains of questionable value in teaching pathology the authors are wise in condensing the case histories used in this volume. Many unnecessary words and phrases have been eliminated without detracting from the clarity of the explanations.

A proper increase in the amount of space allotted to neoplasms has been made. The sections on the bacterial and the parasitic diseases are still the best in their respective divisions of any of the commonly used texts of pathology. In a future edition there could be added chapters on the pathology of skin and of the special senses. This would enhance its value and enable the student to be grounded in the pathologic changes of the more common entities seen in these specialties. Consideration might also be given to the possible inclusion of a section on radiation effects.

The two column format of the printed page makes reading less fatiguing, more accurate, and more rapid. This volume may be wisely used by the student and practitioner either for preliminary study or as a review of the fundamentals of pathology.

MARK WEEKLOCK.

DISEASES OF THE EAR, NOSE AND THROAT. By William Wallace Morrison, M.D. New York: Appleton Century Crofts, 1933.

ESSENTIALS OF PATHOLOGY. By Lawrence W. Smith, M.D. F.R.C.P. and Edwin S. Gault, M.D. F.R.C.P. 3rd ed. Philadelphia and Toronto: The Blakiston Co. 1933.

CHRISTOPHER'S *Minor Surgery* is so well known and so widely used that little needs to be said concerning the general content of the volume. The scope of the book, according to the preface is the consideration of the pathogenesis, diagnosis, and treatment of conditions which are included in the surgical operations performed by the general practitioner by the physician who does not have ready access to large hospitals or contact with specialists in surgery and by the physician who was unable to serve the long apprenticeship necessary for the practice of surgery. A sincere effort has been made to avoid provincialism. Direct quotations are used extensively, an excellent method by which to present the ideas of experts in a particular field and, as the author points out, the fairest method of giving credit to these men. In addition the method serves admirably to introduce many leaders in surgery through some of their best work to surgical intern and resident.

The first three chapters deal with wounds and infections, and the succeeding four chapters deal with burns, foreign bodies, injuries by electricity and circulatory disturbances. Subsequent chapters discuss injuries, infections, deformities and tumors of the head, neck, trunk and extremities. The male and female genitourinary organs are covered in separate chapters and the valuable sections pertaining to preoperative and postoperative care, minor surgical technique, and the duties of the surgical intern have been retained.

One might be somewhat skeptical as to the necessity of another edition four years after publication of the fifth edition but in reading this volume the reviewer concluded that the sixth edition is amply justified by the author's continued effort to supply information of latest advances and most approved methods of treatment. The length has been increased by approximately fifty pages. The paper typography and binding are excellent, as are most of the illustrations. References have been moved from footnote position to the ends of the various chapters. The incredible number of references is a gauge of the extensive coverage of the field and the merit of the volume is greatly enhanced by the bibliography. For example there are 451 references, designated by number in the chapter on open wounds. The criticism may be carping but with references at the end of the chapters, one would prefer to have them arranged in alphabetical order. While this edition has been extensively revised, the general format remains unchanged.

As would be expected, in fields in which considerable progress has been made extensive revision has been necessary and several new sections have been added. The discussions of antibiotics and sulfonamides have been greatly expanded, as have the sections on thrombophlebitis, phlebotrombosis, burns, varicose veins and pilonidal cysts. New material, in this edition, includes information concerning gelatin

Minor Surgery. By Frederick Christopher, B.S. M.D. F.A.C.S. 6th ed. Philadelphia: W. B. Saunders Co. 1944.

sponges and oxidized cellulose early postoperative ambulation Lund's tables of skin areas excision and closure of bedsores, treatment of malignant melanoma, placement of neck incisions refrigeration an esthesia as well as consideration of other recent advances. Other sections have been extensively amplified particularly those dealing with wound healing certain fractures and sprains skin grafting with a discussion of the Padgett dermatome blood transfusions the Rh factor and fluid and electrolyte balance.

The sixth edition with revisions and additions of material is the best book in its field.

B. MARDEN BLACK.

FOR his recent book Dr. Walter has taken the same title which Schimmelbusch used in 1892 namely *The Aseptic Treatment of Wounds*.¹ The difference in the size and scope of these two books is indicative of the progress that has been made in this field in the last 50 years. The introductory chapters show graphically the contributions made during the overlapping careers of many different men and the gradual evolution of the philosophy of asepsis over a period of two hundred years from Charles White to Johann von Mikulicz Radecki, the former stressing cleanliness and isolation and the latter emphasizing the importance of masks and gloves and the dangers of wound contamination from the air.

Dr. Walter has brought to this problem his early technical training which he has applied to the mechanics of sterilization of dry goods instruments, solutions may more the whole environment of the operative field. He has stressed the belief that the surgeon himself should understand these principles, in order that he may direct and control these processes rather than turn the responsibility over to a constantly changing personnel among his assistants. However the book is written not only for the surgeon but for the technical assistants in the operating room so that they too may understand the necessity for the minutiae of detail required to prevent the entrance of bacteria into the wound of the patient particularly those which may come from the mechanical devices involved in sterilization.

In his delineation the author is greatly aided by the excellent line drawings of his co-author Mildred Coddington who with keen understanding follows through the steps of the preparation of the patient, the personnel and the sterile field clearly illustrating the closing and opening of laparotomy kits, surgical drapes surgical gowns pads, masks and the arrangements of instruments.

The book stresses the importance of the controls required to make foolproof the steam sterilization both for routine and emergency work and the care of the instruments both before and after this procedure. The rationale of the surgical scrub-up both for the doctors' hands and for the operative field is thor-

oughly explained. The dangers of contamination by air borne bacteria are carefully considered with special reference to the bacteria which are brought in by the operating personnel on their clothing and shoes and particularly in their noses and throats, from which organisms can so readily be distributed to the sterile field or into the wound where they may grow rapidly because they have come so recently from a similar human environment.

In the operating room technique itself Walter stresses the importance of team work and here Mildred Coddington comes to his aid with innumerable illustrations which should be of great value to any operating room staff which desires to work with optimum efficiency and safety.

The book lays special stress on the terminal sterilization of instruments and textiles from septic cases which are potential sources of bacterial contamination. Their care is often neglected in many hospitals. Contamination from this source can be reduced to a minimum by the intelligent application of the principles involved. This danger can be controlled almost single handed by a conscientious scrub-up nurse.

Dr. Walter goes into the necessity for great care in the preparation of parenteral fluids including blood and plasma and the importance of the avoidance of reactions from the administration of these fluids.

The author also emphasizes the value of carrying the principles of asepsis into the wards where daily dressings are done, in order to avoid the spread of infection from one patient to another and the transfer of organisms from patients to attendants and attendants to patients. This also is an important phase of asepsis which is often neglected. It has recently been re-emphasized during the war period when soldiers were brought into hospitals in great numbers carrying with them the contamination from the fields of battle as well as the organisms causing nonsurgical communicable diseases.

I have no hesitation in saying that this book should be part of the equipment of every hospital operating room and be read and understood by every surgeon and his assistants.

FRANK L. MELENTY

IN these days of schools of psychiatry with each group supported by zealous followers who believe that only their method is correct, it is difficult to prepare a book of psychiatry which would not be confusing to the uninitiated. Certainly the medical student, completely unaware of different philosophies and ideologies in a rapidly expanding specialty can develop no well organized concept of human behavior and its aberrations when this difficult subject is presented from so many different angles.

It is gratifying therefore to read the book *Modern Clinical Psychiatry*² which had been established earlier as a textbook and find the entire subject of psychiatry treated temperately yet extensively and comprehensively. Dr. Noyes himself is apparently a follower of Adolph Meyer and his philosophy of psycho-

¹THE ASEPTIC TREATMENT OF WOUNDS. By Carl Walter, A.B. M.D. Illustrated by Mildred B. Coddington, A.B. M.A. New York: The Macmillan Co., 1948.

B. MARDEN BLACK.

FOR his recent book Dr Walter has taken the same title which Schummelbusch used in 1892 namely *The Aseptic Treatment of Wounds*¹. The difference in the size and scope of these two books is indicative of the progress that has been made in this field in the last 56 years. The introductory chapters show graphically the contributions made during the overlapping careers of many different men and the gradual evolution of the philosophy of asepsis over a period of two hundred years from Charles White to Johann von Mikulicz Radecki, the former stressing cleanliness and isolation and the latter emphasizing the importance of masks and gloves and the dangers of wound contamination from the air.

Dr Walter has brought to this problem his early technical training which he has applied to the mechanics of sterilization of dry goods instruments, solutions may note the whole environment of the operative field. He has stressed the belief that the surgeon himself should understand these principles in order that he may direct and control these processes rather than turn the responsibility over to a constantly changing personnel among his assistants. However the book is written not only for the surgeon but for the technical assistants in the operating room so that they too may understand the necessity for the minutest of detail required to prevent the entrance of bacteria into the wound of the patient particularly those which may come from the mechanical devices involved in sterilization.

In his delineation the author is greatly aided by the excellent line drawings of his co-author Mildred Coddington who with keen understanding follows through the steps of the preparation of the patient the personnel and the sterile field clearly illustrating the closing and opening of laparotomy kits, surgical drapes surgical gowns pads masks, and the arrangements of instruments.

The book stresses the importance of the controls required to make foolproof the steam sterilization both for routine and emergency work and the care of the instruments both before and after this procedure. The rationale of the surgical scrub-up both for the doctors' hands and for the operative field is thor-

oughly explained. The dangers of contamination by air borne bacteria are carefully considered with special reference to the bacteria which are brought in by the operating personnel on their clothing and shoes and particularly in their noses and throats, from which organisms can so readily be distributed to the sterile field or into the wound where they may grow rapidly because they have come so recently from a similar human environment.

In the operating room technique itself Walter stresses the importance of team work and here Mildred Coddington comes to his aid with innumerable illustrations which should be of great value to any operating room staff which desires to work with optimum efficiency and safety.

The book lays special stress on the terminal sterilization of instruments and textiles from septic cases which are potential sources of bacterial contamination. Their care is often neglected in many hospitals. Contamination from this source can be reduced to a minimum by the intelligent application of the principles involved. This danger can be controlled almost single handed by a conscientious scrub-up nurse.

Dr Walter goes into the necessity for great care in the preparation of parenteral fluids including blood and plasma, and the importance of the avoidance of reactions from the administration of these fluids.

The author also emphasizes the value of carrying the principles of asepsis into the wards where daily dressings are done, in order to avoid the spread of infection from one patient to another and the transfer of organisms from patients to attendants and attendants to patients. This also is an important phase of asepsis which is often neglected. It has recently been re-emphasized during the war period when soldiers were brought into hospitals in great numbers carrying with them the contamination from the fields of battle as well as the organisms causing nonsurgical communicable diseases.

I have no hesitation in saying that this book should be part of the equipment of every hospital operating room and be read and understood by every surgeon and his assistants. FRANK L. MELENEY

IN these days of schools of psychiatry with each group supported by zealous followers who believe that only their method is correct, it is difficult to prepare a book of psychiatry which would not be confusing to the uninitiated. Certainly the medical student, completely unaware of different philosophies and ideologies in a rapidly expanding specialty can develop no well organized concept of human behavior and its aberrations when this difficult subject is presented from so many different angles.

It is gratifying therefore to read the book *Modern Clinical Psychiatry*² which has been established earlier as a textbook and find the entire subject of psychiatry treated temperately yet extensively and comprehensively. Dr Noyes himself is apparently a follower of Adolph Meyer and his philosophy of psycho-

¹THE ASEPTIC TREATMENT OF WOUNDS. By Carl Walter A.B. M.D. Illustrated by Mildred B. Coddington, A.B., M.A. New York: The Macmillan Co., 1948.

²MODERN CLINICAL PSYCHIATRY. By Arthur E. Noyes, M.D. 3d ed. Philadelphia and London: W. B. Saunders Co., 1948.

biology but he reviews all the earlier contributions of Kraepelin, Bleuler, Janet, and finally culminates in a complete objective evaluation of the psychoanalytical theory of behavior and its applicability in therapy. The different spheres of thought are handled in such a way as to leave the student clear as to what is definitely established.

At the same time the practical aspect of the applicability of the various regimens of treatment is not lost sight of. The book contains comprehensive chapters on institutional care, special procedures like hydrotherapy, occupational therapy, recreational therapy and psychotherapy, plus the more recent methods of insulin and convulsive shock therapy. The treatment of neurosyphilis by fever and penicillin is discussed comprehensively. Even frontal lobotomy is evaluated. A chapter is included on psychosomatic medicine in which the relationship of psychiatry to

general medicine is well delineated. Psychotherapy is reviewed in its various disciplines. The closing chapter is on child psychiatry which gives the reader an idea of some of the disturbances that may be encountered in the young.

All in all the author covers the field of psychiatry in a broad manner. His own experience and background are such as to enable him to have a mature opinion about the various techniques of the care of the mentally ill, and with many of the therapies like shock therapy and the fields of psychotherapy beginning to come of age, an objective measure can be made and is presented.

I enjoyed reviewing this book and can recommend it for medical students and for general practitioners. It is a book that could well be frequently used by every psychiatrist no matter what his personal philosophies. BENJAMIN BOEKER.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

COLLECTIVE REVIEW

VENOUS OBSTRUCTION IN THE UPPER EXTREMITY (PAGET-SCHROETTER'S SYNDROME)

A Review of 320 Cases

E. S. R. HUGHES M.D., M.S. F.R.C.S. (Eng.) London England

IN 1875 a series of lectures that had been delivered by Sir James Paget was published in the course of one of these entitled *Gouty Phlebitis*,¹ he described 2 cases in which the clinical features, he believed were attributable to a thrombosis of the main veins of the upper extremity (187).

A man about 50 years old, thin and moderately muscular and usually healthy observed, during a September that his right arm was growing larger and as he thought, stronger, and fitter for work. But, as it still increased, it became inconveniently heavy, and certainly weaker and then he applied for advice. I found the upper arm two inches more in circumference than the left, and the whole limb enlarged in the same proportion. It looked full, round, and muscular and felt firm, and oedematous, not only in the subcutaneous tissue but throughout the skin was tense, cool, and pale. In nearly four inches of its course the axillary vein felt large, hard, and cord-like and in one or two spots over it pressure caused pain but with this exception no pain was felt in any part of the arm. Some of the superficial veins in the arm, and over the upper and front part of the chest were enlarged, and when the arm hung down for a long time the hand became dusky. No cause whatever could be traced for this condition. No injury or pressure no known inheritance of disease no disturbance of the general health, past or present.

With the help of hot douche, warmth, and friction the swelling of the arm very gradually subsided and, as it did so, the cord like feeling of the obliterated axillary vein became more distinct. A year elapsed before the vein regained its completely natural condition but it has now for more than five years been well.

Honorary Surgeon, Connaught Hospital, London and a Leverhulme Scholar of the Royal College of Surgeons of England.

Very similar to this case was that of a regimental servant, 57 years old, previously healthy and very active, who was sent to me on April 25th 1885 by Mr. Bossey on account of the condition of his right arm. This was swollen and when it hung down, he had a feeling of weight and fulness as if the blood could not return from it. The arm was, indeed, about a quarter or a third larger than the other but its chief enlargement felt as if due to great muscular development. Besides this, however it had probably some general swelling which might be from slight oedema of its deeper tissues, its subcutaneous veins were all overfull there were small bluish spots over the deltoid, as if from small clusters of varicose veins, and the veins over the right pectoral muscles were fuller than those over the left. This condition of fulness extended as high as the deltoid's origins the shoulder especially was remarkably broad and large, and there were fulness and some prominence of the upper part of the right great pectoral. The heart's action and sounds were natural so was the pulse at both wrists, equal and moderately full. It was uncertain how long this state of the arm existed. It had been observed only a week its rate of increase was unknown. The patient remained in about the same condition till May 4th, when he was taken into Hospital, and ordered milk diet six leeches every third night and three grains of Mercury with chalk every night and morning. He was under this plan for about a fortnight, and certainly improved, the arm decreasing, and its veins becoming less full. Then he had an attack of scarlatina, and while this was running its course all signs of the affection of the arm disappeared. It regained its natural size the veins were scarcely fuller than in a healthy man he lost the sensation of numbness, and he believed himself well at the end of May.

In 1884 von Schroetter reported a similar happening in the right arm of a healthy painter who was working at the time of the onset. Schroetter believed that the axillary vein was damaged and

Fig. 1. Age of patients in years. The graph rises abruptly to its highest level between 20 and 25 years. The incidence gradually declines and relatively few cases are seen after the age of 50 years.

Fig. 2. Relation of age in years to sex. Males— Females. There is no significant difference in the ages at which the two sexes are affected.

was subsequently obstructed by a thrombus. Damaschino is said to have studied a similar case 3 years later. These cases are to be distinguished from the one described in 1894 by Letulle and Meslay in which thrombosis of the subclavian and internal jugular veins complicated extensive carcinoma and from those reported by Bouchut, Humphry, Meslay and others in which thrombosis of the subclavian and axillary veins occurred in the terminal stages of advanced cardiac failure.

No further cases of the type described by Paget and Schroetter appeared in the literature until 1910 and 1911 when Schepelmann (189-190) published his observations on a boy of 22 years who developed pain and swelling in the left arm following overexertion controlling high spouted horses. Ruge and Unger both gave an account of cases in Germany in 1911 and at the Fortieth Congress of Surgeons in Berlin in the same year Heinecke reported 3 cases while Rosenthal added 2 more the following year. German authors continued to show considerable interest in the syndrome further examples were published by Baum, Hollander and Finkelstein. Loehr reviewed the literature in 1929 and added 6 more cases (124) and more recently several large series have been reported (82 125 212 222).

In France, Layrol described a case in 1911 and in 1913 there was considerable discussion on a number of patients presented at the Paris Surgical Society (22 45 141 164, 174 181 193). Further cases soon followed and by 1932 Cottalorda was able to publish a long review but relatively few have since been reported in the French literature.

In 1913 Gautier reported 2 cases in Switzerland and he quoted a thesis written a year earlier on the subject by a compatriot, Madame Bogdanoff. Winterstein added 4 more cases in 1925 reviewing the literature at the same time. Vossenaar described a case in Holland in 1913 and Goudsmit reported another some years later. In Scandi-

navia, the first cases were published in 1929 and 1932 by a Dane, Thomsen (202-203), while Ljunggren, from Sweden, reported a third in 1936. Excellent reviews have recently been published by Roelsen of Denmark (177-178).

Professor Ranzi, of Pisa (1849) has been accredited as the first to suggest "effort" as a cause of thrombosis (161-204). Carere discussed the condition in 1911 and several comprehensive reviews have been written by his Italian colleagues, Pinelli, Paggi (153), Piccagli, Tomasi, and Pozzi.

The first cases to be reported from South America were those of Chutro of Argentina, in 1914 and 1915 (32-33). In 1920 Pavlovsky gave an account of 3 cases, and 3 more were reported by Ivanissévitch (94) 2 years later. In North America, Wilson described 2 cases in 1922, while Lowenstein in 1924, made the first real attempt to find the solution to the problem of etiology. In recent years the condition has aroused much interest in the United States.

Willan discussed the cases of 3 patients in 1918, and 10 years later Gould and Patey (70) reported 8 more in London and described some original work on the subject. However the syndrome has never excited much attention in Great Britain and relatively few cases have been described.

TERMINOLOGY

The uncertainty which surrounds the etiology and even the pathology of this condition is reflected in the varied terminology. Most authors have used the terms "thrombosis" or "primary thrombosis of the axillary (subclavian) vein." Those who are impressed by the possible etiological significance of injury to the vein, have termed the lesion "traumatic," "strain," or "effort thrombosis," while others have preferred to add the prefix "so-called," for example "so-called traumatic thrombosis."

Loehr (125) has suggested that the term "intermittent venous claudication" is as apt as any

Fig. 3. Relation of the age in years to the side affected. Right—Left. There is no significant difference between the ages at which the two sides are affected.

other and this has been supported by other German writers. But Hauge believes it to be inaccurate because recurrence of symptoms after exercise is more probably due to inability of the collateral circulation to deal with the increased volume of blood rather than to any intermittent obstruction; he suggests that the condition be termed 'venous stasis'. MacCarthy has described his case as traumatic venospasm and there is no doubt that this was a feature of his case, but this has been unproved in the majority of cases, and does not appear to be the underlying factor in any case. Acute (subacute) oedema of the arm is a most unsatisfactory term.

The association of a more or less acute venous obstruction in the upper extremity of an otherwise perfectly healthy person constitutes a syndrome which in the absence of accurate knowledge of the etiology and pathology can be called the 'Paget-Schroetter syndrome,' after the first two to describe it as a clinical entity.

CLINICAL FEATURES

Age. Buxton stated that he had seen the condition in a patient of 75 years of age but gave no other details. Gautier reported it in a man of 72 years; this patient appears to have been perfectly healthy although he had a positive Wassermann reaction. Moure's case (142) was that of a woman of 71 years who developed a subclavian thrombosis after sustaining a fractured clavicle which gave rise to a fatal embolism 4 days after the injury. It is doubtful if either of these last 2 cases can be rightfully included in the disease under discussion. Salmon and Audier reported a patient of 70 years, Lenormant and Mondor one of 68 years, while Stover and Herrell, and De Bakay, Ochsner and Smith have had instances in people of 66 years. On the other hand the youngest patient so far observed has been a girl of 11 years, observed by Rosenthal, in whom the onset followed a very light game with a ball. Lapeyre has seen a boy of 14 years affected after carrying a

Fig. 4. Sex. Males are affected in 78 per cent of the cases, females in 22 per cent.

Fig. 5. Side. The right side is affected in 66 per cent of the cases, the left in 34 per cent.

heavy bucket of water. The onset has been noted on occasions, in children of 15 years (43, 209) and 16 years (43, 159) while several authors have had 17 year old patients (92, 132, 150, 154, 155, 158, 164, 178, 201, 220) (Fig. 1).

Sex. The predominance of the male sex has been recorded by all reviewers. All 3 of Willan's patients were males as were the 3 patients in the cases published by Heinecke and Pavlovsky (155), Kinzel, Loehr (125), Kux, Kaplan (101) and Morton each reported 4 cases, in all of which the patients were males, as were all 8 in the cases reported by Gould and Patey (70). Seven of the 8 patients in Zehnder's series, 6 of the 7 in Herlyn's, and 5 of the 6 in Barker's were males, and there was only 1 female in each of the series of 5 reported by Wagner and Sampson (184).

On the other hand 5 of the 7 patients in the cases published by Roelsen in 1939 were females (177) and 3 of the 7 patients seen by the same author in 1944 were also females (178). Three of the series of 5 cases published by both De Bakay, Ochsner and Smith and Hughes were those of females, as were half of those reported by Loehr (124) and Hunter. Both of Clute's and both of Goudsmit's patients were females. The relative incidence of males and females is shown in Figures 2 and 4.

Side. The right arm is involved more frequently than the left (66%). This was conclusively demonstrated in Paget's review in 1933 (153) and apart from a few exceptions (25, 53, 78, 80, 124

125 133 145) is further exemplified in the individual series that have been published. As a result of this right-sided predominance, it has been suggested (209) although incorrectly that whenever the left arm is affected the patient is left handed or has used the left arm in some unusual manner. For example, Schepelmann's patient is said to have used his left arm to control the horses, and Winterstein who had 2 such instances in his series pointed out that 1 occurred in a weaver whose work involved extra strain on his left arm, and the other occurred in a man engaged in lifting heavy bales of cloth who used his left arm more than his right. The relative frequency with which the two sides are affected is demonstrated in Figures 3 and 5.

Onset. The clinical features are characteristic when the condition has fully developed, but the initial symptom and mode of onset show some variation.

1 The arm becomes swollen in 57 per cent of the cases, sometimes slowly but more often rapidly and occasionally quite suddenly. This is accompanied by a sensation of tightness and of fullness and the limb feels heavy and stiff.

2 In 34 per cent of the cases the first symptom might be spontaneous pain in the arm or shoulder or it may be perceived only on movement; there is sometimes a sensation of undue fatigue in the arm.

3 In 6 per cent of the cases there is discoloration, or prominence of the veins in the arm or on the chest wall.

4. Two per cent of the patients on performing a movement have suddenly experienced a peculiar sensation in the shoulder or arm as if something had given way or "snapped" (114, 128, 150 171 211).

5 Two patients experienced *paresthesia*, a tingling sensation in the arm, immediately prior to the development of the typical clinical features (50, 114).

6. In 1 of Roelsen's cases the first symptom was pruritus in the affected arm (178).

7 Routhier's patient complained of a sudden onset of "paralysis" of the left arm while Barker, Kux, and Unger have noted weakness as an initial symptom.

In some cases the onset is acute and in others quite gradual; a sudden onset may occur in patients unexposed to any provocative activity while a gradual development occurs after an apparently definite causal trauma. Whether the onset be sudden or gradual, the first symptom may be either pain or swelling. Veal and Huxley (207) believed that a gradual onset was nearly always

due to malignancy with initial symptoms of slight enlargement of the arm and unusual fatigability. This appears to be an oversimplification because in many of the cases reviewed the condition developed insidiously without any evidence of malignancy at all. Moreover, many patients noticed aches or pains in the shoulder or arm for some days prior to the appearance of the swelling and discoloration. Nor can one agree with Goldberg and Foley and others who believe that it is atypical for the onset to be gradual and unaccompanied by pain.

In 39 instances (13% of the number in which the onset is described) the patient awoke to find that the arm was swollen or blue, or ached or felt heavy.

Swelling. This has been noted in every case but 2 (40 195) and it is doubtful whether these 2 cases should really be considered as examples of the condition. In some cases the swelling only becomes apparent after the performance of some form of exercise. The whole arm is affected, from finger tips to shoulder and usually the swelling spreads on to the chest wall and may extend into the neck (136). Even in cases in which the swelling is considerable, pitting with the thumb is frequently impossible because of its firm nature. It might begin quite insidiously and even remain unnoticed by the patient until pointed out by an other or until the sleeve of a garment or a ring can no longer be worn. In Paget's first case the patient observed that "his right arm was growing larger and," as he thought, stronger and fitter for work. On the other hand, as Matus, and De Bakker Ochsner and Smith (43) have emphasized, an occasional feature of the syndrome is the rapidity with which the swelling spreads over the arm.

Extreme distention of the veins must largely account for this swelling; such venous overfilling is easily demonstrated by the distended appearance of the superficial veins, by their failure to collapse on elevation, and by the marked rise of the venous pressure. Excessive interstitial fluid plays a less important role, although it may be the chief factor for example, in some cases the swelling is soft and compressible and some surgeons have noted a considerable drainage of fluid from incisions in the arm.

Pain. This is a variable symptom and may never be present (67 72 178 207 215). The swelling frequently causes a dull ache in the arm, which is usually mild but may be severe such "tension" pain is diffusely referred over the whole of the arm. In some cases, pain is localized to the region of the shoulder girdle particularly the

axilla (118 177), in these circumstances it probably originates from the primary lesion itself whether it be complicated by a thrombus or not. When a thrombus exists and propagates itself along the brachial vein it may be followed by pain referred to the medial side of the arm (215). Sometimes the patient experiences pain often intense only after exercise of the arm this being presumably due, partly to a retention of metabolites and in part also to the swelling that the exercise provokes. The second case reported by O'Regan was unusual in that the pain was situated high up on the right side of the chest and was aggravated by deep breathing this was shortly followed by the appearance of the signs of venous obstruction in the right arm.

Discoloration. The arm develops a cyanotic hue although occasionally it becomes red or pink (64, 84, 101 178) and may even become white (189). This discoloration which is nearly always to be observed at some time during the illness, is usually diffuse but may be mottled (63 131 158). Roelsen (177) noted in one of his cases that even before the onset of the disease the hands became blue and black in cold weather. Bruising of the skin has been observed and Roelsen (178) described the appearance of 'phlebectasis'.

Venous distention. Almost without exception the disturbance in the circulation has been reflected in the superficial venous system. These veins become engorged and previously unnoticed veins about the shoulder and neck become apparent as the circulation develops through collateral channels. These distended collateral vessels may be the first evidence of the disease (37 70 177 178) and are usually apparent at the initial examination although excessive subcutaneous tissue or considerable swelling may obscure them at first. Sampson, Saunders and Capp (185) have reviewed the anatomy of the superficial veins of the thorax which are involved. There is a group of veins which stretches between the cephalic (and sometimes the basilic) and the external jugular veins, passing across the clavicle and upper part of the chest. A second group passes inferiorly over the thorax and connects the axillary or basilic veins with those of the abdominal wall, including the musculophrenic venae comitantes. This connecting channel is constituted by the lateral thoracic vein external mammary vein, mammary subareolar plexus and epigastric veins. This second group anastomoses with the first and also with the venae comitantes of the internal mammary artery of both sides.

Paresthesia. The pins and needles sensation and tingling have been experienced by a few patients

but there is no particular distribution. One of Roelsen's patients complained of paresthesia in the hand (177). French's patient noticed tingling in the finger tips, while one of Willan's patients referred the sensation to the palm and thumb when the arm was held in certain positions. A patient observed by Rixford experienced tingling in the arm immediately after the onset and another numbness in the hand at night, while Roelsen's second patient in his 1944 series only experienced the sensation after the venography wound in the cubital fossa had suppurated (178). Horton's patient developed tingling in the arm after lying on it another of Roelsen's patients felt pins and needles in the arm when it was dependent (177).

Pruritus. Roelsen (178) reported the case of a man of 35 years who rubbed his right arm to relieve a persistent itchy sensation within a very short time the arm was found to be diffusely swollen and discolored with distention of the superficial vessels.

Movements. Wilson described complete paralysis of the muscles in the affected arm in both his cases and attributed it to pressure on the brachial plexus by a thrombus. Others have found varying degrees of temporary paralysis (22 26 77 122 129 134 143 144, 160 164, 181) but such observations lose much of their significance without uniform expression of muscle power.

The passive movements of the limb are generally unrestricted but there may be some limitation as the result of pain and swelling.

Palpation. Many authors have found abnormal conditions on palpation of the axilla, and it seems certain that a thrombosed vein is sometimes if not frequently the responsible factor. Gould and Patey (70) noted that the axillary vein felt like a cord from its commencement to the clavicle. Gerster found a cord like structure very firm fixed, immovable mass 2.5 cms in diameter which could be followed for about 6 cms. Hauge described the axillary vein as 'feeling like a cord thick as a pencil and increasing to more than the thickness of the finger at the upper part of the shoulder insensitive'. Ivanissevitch, McGoogan and Simmons and Kaplan (101) palpated hard tender cords in the axilla which could be traced down the arm to the midforearm, and occupied the track of the brachial, basilic, and median basilic veins. Although most writers have described a cordlike thickening in the axilla both Guyott and Jeaneney and O'Regan found localized mobile tumors of small size and tender on pressure. It is possible that these were thrombi as believed by the authors. On the other hand Cottalorda found no thrombus at operation on one of his patients.

despite the fact that it was regarded as certain that such could be detected clinically. Roelsen (178) after careful investigation of his patients, evidently felt that it was a difficult matter to decide whether the vein was thrombosed or whether it was merely distended with fluid blood.

In some cases the axilla has been tender without the presence of any palpable lump (23 70 173, 184, 215) while French and Rixford have noted a delayed appearance of a cordlike thickening along the brachial vessels. Others have not been able to demonstrate any cord tumor or tenderness, although the other clinical findings are in every way similar to those in cases which possess positive signs (3 64 86 94, 101 103 128 131 138 141 158 177 183 184 186 200 215).

In a few cases there has been tenderness, and sometimes a lump in the supraclavicular fossa suggestive of thrombosis of the subclavian vein. In Lenormant and Mondor's case the external jugular vein appeared to be thrombosed (118) and Ditter and Walker describe a cordlike induration with a zone of slight redness but non-tender along the course of the cephalic vein.

Venous pressure. Increased venous tension exists in all cases, and on examination this is obvious from the engorged veins of the arm. Veal and Hussey (207) described a technique for measuring venous pressure accurately both in a state of rest and after exercise of the arm; this constitutes their exercise test. Hauge also utilized the abnormal rise of venous pressure on exercise in his "provocative test" he estimated the venous hypertension clinically.

The normal venous pressure varies from 5 to 12 cm. of water. In this syndrome, a very high venous pressure has been observed in the resting arm on several occasions. Kaplan (102) had 2 cases with a resting tension of 21 and 41 cm., respectively. Salmon and Audier, Greenfield and Roca and Lazaroni have also noted marked increases at rest.

In some cases the resting venous pressure has been only slightly elevated, but an exaggerated rise follows exercise. In Roelsen's 1939 series (177) one patient had a resting venous tension of 9 cm. on the affected side, a rise of 4 cm. above that on the normal side, but this difference increased to 21 cm. on exercise. A similar case was recorded by the same author in 1944 (178) and Wilcutts and Shelburne reported a case in which the patient presented a difference of 3 cm. between the arms at rest, but after exercise the normal side rose to 9 and the abnormal to 37 cm.

Although this accurate estimation of the venous pressure is of considerable interest, the

procedure is for the most part unnecessary and should be reserved for the occasional case in which the diagnosis might be in doubt.

Collapse of the veins on elevation of the arm. Several authors have noted that the superficial veins empty slowly on elevation of the arm (48, 101 102, 150 184). Keener, Canty and Prevost, and MacCarthy found that they may fail to empty at all, while Kaplan (102) observed in one of his patients that some of the veins emptied but others remained distended.

Circulation time. The circulation time from the affected arm has been investigated by several observers. Calcium gluconate in a 10 per cent solution has usually been employed for this purpose. As might be anticipated, in every case investigated, the circulation time has been prolonged (37 48 72 101 102 158, 207 216).

Oxygen saturation of the venous blood. Veal and Hussey (207) found a lowered oxygen content of the venous blood in their patients, and this has been confirmed in other cases (72 86).

Cruikshank regarded the test of such importance that although there was neither swelling nor discoloration in his case, he believed that a diagnosis of axillary vein obstruction was justified because the oxygen saturation of the venous blood was only 43 per cent as compared with a normal of 70 per cent on the opposite side.

Skin absorption time. Salmon and Audier and Wilcutts and Shelburne injected 0.1 c.c. of normal saline solution intradermally and noted its disappearance in 50 seconds from both the normal and the affected arms. They are the only investigators to record such a test in this condition.

These last three investigations, like the measurements of venous pressure are of undoubted value in a case in which the diagnosis might be obscure. However, as this is rarely the case their practical application is limited.

Arterial pressure. There is no clear agreement as to the state of the arterial tension in the affected arm. Bazy, Kaplan (102), Greenfield, and MacCarthy have noticed the radial pulse to be weaker but most observers have been unable to detect any difference. The blood pressure in the involved arm also shows no appreciable departure from the normal level in most cases. In one of Sampson's cases (183) the blood pressure was found to be the same in both arms, but in another the pressure on the affected side was 100/70 mm. of mercury while on the normal side it was 135/70 mm. of mercury, six days later there was still a depression although the pressure was approaching normal. Other au-

Fig 6 Normal venogram. The basilic, brachial, axillary and cephalic veins are well filled but the subclavian vein is visualized. The veins show localized dilatations above valves. Before terminating in the axillary vein, the cephalic vein exhibits a characteristic curve (due to the pectoralis minor muscles).

Fig 7 Normal venogram. The basilic, brachial, axillary and cephalic veins can be seen and the dye traced beyond the first rib into the subclavian vein (arrow). There are no valve dilatations. The distal half of the axillary vein is apparently narrow while more proximally it shows reduplication. The cephalic vein displays its characteristic curve.

thors have also recorded a lowered blood pressure in the involved arm (71, 89, 101, 103, 126, 139, 218). On the other hand Veal and Hussey (207) have found that the sphygmomanometer reading is often from 10 to 15 mm. of mercury higher on the affected side and this is confirmed by the observations of others (39, 51, 131, 132, 136, 139, 175, 196, 218, 222). Clute and Rixford have both observed considerable differences between the readings from the two arms.

Oscillometry. The oscillometric index has been measured by a number of investigators but the readings have varied. The index may be increased (39, 101, 102, 177) or decreased (17, 37, 101, 103, 104) or there may be no detectable difference between the two sides (73, 74, 78, 101, 162, 177, 216). In one of Roelsen's patients a normal reading was observed at rest but during exercise the index became greater in the affected arm (177).

Temperature of arm. A rough clinical estimation of the temperature of the affected arm has been made by many but very few accurate recordings have been attempted. Freidland and Farber, and Roca and Lazaroni have found the arm to be warmer when measured with the thermocouple, whereas Horton noted it to be from 0.2 to 1.0 degree C. cooler. Many writers have had the impression that the arm was cooler but others have found it to be warmer.

Lenography. Except on the rare occasions when a cervical rib (4, 83, 134, 162) or an aneurysm of the aorta (119, 197) or some such other cause for obstruction to the venous flow from the upper

extremities has been detected by direct roentgenography, this line of investigation has been of surprisingly little value. Blood vessels are only displayed by such means when their walls are calcified so that it is necessary to employ radio-paque solutions as used in urography in which the iodine complex is organically combined and thus rendered comparatively inert. Other substances have been employed with equally good effect e.g. diodrast (102, 198) and colloidal thorium dioxide (16, 101). The author uses a 50 per cent w/v solution of pyelosis (diodone) which contains 49.8 per cent by weight of iodine.

One of the veins in the cubital fossa is selected for the injection. Andersson believes that injection into the median basilic vein results in the most satisfactory picture. This vessel courses proximally on the medial side of the arm and pierces the deep fascia at about the level of the deltoid tuberosity to join a vena comitans of the brachial artery; the resulting venous trunk after a short course is further augmented by the profunda vein before terminating in the third part of the axillary vein. Kaplan and Katz (103) and others prefer to use the median cephalic vein which runs up the lateral side of the arm into the groove between the deltoid and pectoralis major, pierces the clavipectoral fascia on the medial side of the pectoralis minor and finally enters the axillary vein, frequently in conjunction with the acromiothoracic vein. Others have selected the median cubital vein which connects the former two vessels and usually

Fig. 8. Normal venogram. The basilic, brachial, and axillary veins and the distal half of the subclavian vein are visualized (arrow). The dye shadow becomes thin about the site of entrance of the cephalic vein; the latter vessel is not seen.

Fig. 9. Normal venogram. The basilic, brachial, axillary and cephalic veins are easily seen; the distal half of the subclavian vein (arrow) is visualized. The third part of the axillary vein shows an apparent narrowing of its lumen. There is a localized dilatation of the first part of the axillary vein due to the valve which is present here.

communicates with the brachial venae comitantes.

A percutaneous technique is used, although Roelsen (178) and others have exposed the vessel when necessary. A 30 c.c. syringe with an eccentric nozzle is fitted with a 30 gauge needle and filled with the medium. The patient is recumbent with the arm held at 45 degrees abduction. As the dye is rapidly diluted an exposure is taken while the injection is proceeding, 5 c.c. being sufficient to display the veins; however to ensure visualization of a maximum number of vessels, a further exposure is taken immediately after the entire 30 c.c. have been injected. Finally a third exposure is made 30 seconds after the injection is completed to ascertain if any stasis of the blood stream exists.

Normal venograms show considerable variations but there is usually an even, although unequal, filling of the basilic, brachial, axillary and cephalic veins. The opaque medium gradually decreases in density and often disappears in the region of the clavicle because of its dilution by blood flowing in from large tributaries. The subclavian vein, therefore is frequently not visualized except in its third part. Several valves may indicate their presence by localized, uniform swellings of the veins (Figs. 6, 7, 8 and 9).

When venous obstruction is present, the injected solution enters the collateral vessels and, as one would expect, these are almost invariably well displayed in venograms of such conditions. The collateral circulation is usually most apparent on the lateral aspect of the arm and sometimes markedly so (67, 101, 103). It often extends well into the neck and is well displayed in the cases

reported by Hango and Kaplan (103). The vessels may be markedly dilated and extremely tortuous (72, 101).

The basilic vein may not fill (178). It may be visualized in its lower portion only (37) or to the point where it pierces the deep fascia in the arm to join the venae comitantes of the brachial artery (16). Kaplan (101), Wilcutts and Shelburne, and Bruce have noted distention of the basilic vein, most marked above the valves present in the vein. There is no constant appearance of the axillary vein. Stabins described it as "thread-like". Roelsen (178) observed that at the level of the axillary fold is an abrupt ending which continues as very weak and irregular streaks of contrast medium" and in a further case that "there is a poorly filled vein suggesting the axillary vein." Kaplan (101) noted a venous segment which appeared to be a narrowed axillary vein, and Perlow and Barth described a case with "abrupt narrowing of the axillary vein—the lumen is about one-eighth that of the distal portion of the vein and is irregular." On the other hand, in the second case of his second series Roelsen (178) observed partial filling of the basilic, brachial, and axillary veins with the dye lying as a thin coat along the walls of the vessels "the lumen is filled centrally by nonshadow-giving mass which can be followed as a cord in the brachial veins from the elbow to the inlet in the axillary vein and for some distance beyond." In another case the same author noticed a large defect in the same vein. Many writers have stated that they have been unable to visualize the axillary vein at all (16, 37, 67, 68, 101, 103, 103, 158, 178). Wilcutts and Shelburne and Bruce observed dilata-

Fig 10 Venogram of recent case of venous obstruction. The cephalic vein is visualized and the dye can be traced from the termination of this vessel into the axillary vein as far as the middle of the subclavian vein. The basilic and axillary veins are not visualized. Collateral vessels enter both the cephalic and axillary veins. The dilatation of the cephalic, the presence of collaterals entering this vein as well as the terminal portion of the axillary vein, and the presence of dye in the subclavian vein all indicate obstruction in the proximal half of the subclavian vein. Thrombosis of the axillary vein, which may be present, is a secondary phenomenon due to stasis and intimal injury from overdistention.

tion of the vein presumably due to an obstruction at a higher level, while Mason, Hauge, and Perner and Cohn claimed to have located the obstruction in the region of the first rib. Demel and Sgalitzer reported a case in which the venogram showed a slight indentation of the subclavian vein which they regarded as due to an apical lesion, while in another they could demonstrate contrast defects due to a thrombosis of the brachial and axillary veins, and partial thrombosis of the subclavian vein.

The cephalic vein is frequently displayed when the median basilic or median cubital veins are injected although a separate needle into this vein may be required. Ditter and Walker visualized the whole of the cephalic vein in their case but at its termination it did not appear to empty into the axillary vein but assumed a collateral and devious course to enter the external jugular vein. Some have been able to demonstrate this vessel to the region of the clavicle (16 136 178) and others to the upper third of the humerus (67 103 158). Kaplan (101) visualized the vessel to the junction of the upper one third and lower two-thirds of the humerus at which point there were numerous collaterals on the lateral surface of the arm. A venous segment could be seen at the point

Fig 11 Venogram of a long-standing case of venous obstruction. The dye passes proximally by way of collateral vessels. The cephalic vein is tortuous and ends, not in the axillary vein but in a vein which crosses the clavicle to join the external jugular vein.

where the cephalic vein should enter the axillary vein. Roelsen (178) injected one patient 3 days after the onset, the median cubital vein was selected with the needle directed toward the basilic vein. All the solution ran back into the cephalic vein which filled and continued in a well developed collateral circulation in the deltoid region. The same author noted in 2 other patients that the vessel was much more distended than usual (Figs. 10 11 12).

The only constant feature of these venograms is the overdeveloped collateral circulation and Loehr (125) has emphasized that such cannot be taken as conclusive evidence of thrombus formation but rather of venous stasis. Roelsen (178) believes

Fig 12 Venogram of external jugular in recent venous obstruction. There is no evidence of obstruction to the external jugular vein indicating a more distal obstruction.

Fig. 3. Venous obstruction of the right arm.

Fig. 4. Same case as in Figure 13 infra-red venography

there are several factors which account for the varying results. The time after the onset at which the venogram has been performed has varied widely and he believes that in some cases a thrombus may have undergone organization and recanalization leaving merely some minor changes in the wall of the vein, not able to give a characteristic picture." A thrombus localized to the subclavian vein, a lesion which cannot be verified radiologically will complicate preconceived ideas as to the interpretation of a venogram, and irritative factors may influence the configuration of the main vessels as well as the collaterals.

In one of Zehnder's patients there was no difference between the venograms obtained from the normal and abnormal arms while Roelsen (178) also had a normal venogram although there was some evidence of stasis.

It is difficult, in view of these findings, to agree with Stabins and others who claim that a venogram shows the site of obstruction and the adequacy or otherwise of the collateral circulation, and hence is a useful investigation. It may indicate where the obstruction begins but it is impossible to judge from the film either its extent or its cause. The efficiency of the collateral circulation is estimated much more satisfactorily by exercise tests and by observing the relation of the latter to the functional ability of the arm. Neither the diagnosis nor the selection of the correct treatment can be influenced by a venogram.

Roelsen (178) observed an aggravation of the swelling in 3 cases after a venogram had been carried out and attributed this to a chemical phle-

bitis superimposed on the pre-existing stasis. Robb and Steinberg investigating a patient with a cardiac condition, injected diiodrast into the veins of an arm and this also was followed by an acute thrombosis of the main veins of the limb. Moreover complications (local or general) may follow the injection of any substance intravenously.

Infra-red venography Superficial veins are clearly displayed by infra-red photography and the overfilled veins characteristic of this syndrome are well demonstrated (Figs. 13, 14, 15, 16, 17, 18).

Constitutional disturbances Constitutional disturbances have been conspicuous by their absence. In fact, there is a considerable contrast in the appearance of the arm, swollen and cyanotic, and in that of the patient, in otherwise normal health. It is true that cases occur in which there is an associated constitutional reaction. For instance, McGoogan and Simmons reported the case of a woman of 42 years, suffering from chronic nephritis and toxemia of pregnancy, who on the fourteenth day after delivery developed axillary and subclavian thrombosis. This was believed, by the authors, to be due to the patient's pulling herself up by grasping the bar at the head of the bed. Her temperature rose to 99.6 degrees and her pulse to 146 and the latter continued to range between 120 and 140 for a week. Wilson recorded a temperature ranging between 99 and 104 degrees in one of his cases. However in the few instances in which the temperature was elevated, it was almost always a transient and very slight rise.

Fig. 15 Venous obstruction of the left arm

In McGoogan and Simmons' patient the tachycardia was extreme but usually the pulse is quite normal even when a mild pyrexia exists.

Several authors have reported cases with a very slight leucocytosis (74, 80, 84, 107, 129, 173) but this was not present in other patients, even those with fever. In no case have any other abnormalities been detected in the cellular content of the blood (except for those noted later and reported by the authors Winterstein and Stover and Herrell).

The blood sedimentation rate has been determined in some cases but it has nearly always been within normal limits (48, 78, 178). Roca and Lazaroni noted a very slight increase of sedimentation in a case 4 weeks after the onset. Roelsen (178) made a similar observation in 4 of his cases although in one of these the rise could be accounted for by suppuration of the venography wound.

DIAGNOSIS

The recognition of a state of venous congestion rarely if ever presents any difficulty. There is a rapid onset of a diffuse firm nonedematous swelling of the arm from hand to shoulder girdle with distention of the superficial veins and a reddish blue discoloration of the hand and forearm. The symptoms may quickly subside but tend to recur with exercise. Accessory investigations, such as venography, measurements of venous pressure, and oxygen content of the venous blood, as well as oscillometric and skin temperature estimations, confirm the presence of this venous stasis if additional proof be needed but provide little or no information as to the cause.

Fig. 16 Same case as in Figure 15. Infra-red venography.

Palpation of the axilla may reveal tenderness and frequently there is a thick firm tender cord occupying the course of the axillary vein. There may be some tenderness and even a cord in the supraclavicular region and down the inner side of the arm. A roentgenological examination is nearly always negative. The patient presents a healthy appearance without constitutional disturbances.

However venous obstruction may occur in the upper extremity as a complication of certain easily recognized conditions.

Cardiac failure. Thrombosis of the main vessels of the upper extremity may complicate cardiac failure but this is rare. It was first described more than 100 years ago by Bouchut, subsequently by Welch, Blumer, and others and more recently by Esselhorn and Janchar and Veal and Hussey (207). The latter reporting 16 such cases. In all these however the involvement of the arm has been but an incident and frequently a terminal incident, in the illness of a patient obviously suffering from serious congestive cardiac failure.

Mediastinal compression. Several cases have been reported complicating an aneurysm of the ascending aorta (119, 197). Other patients have had positive Wassermann reactions but without evidence of an aneurysm (45, 64, 141, 181, 201, 222). In one such case Huard believed the condition to be secondary to a syphilitic mediastinitis, but 6 months later an aortic aneurysm was discovered. A mediastinal tumor is more likely to result in compression of the left innominate vein and cause hypertension in both the jugular and

subclavian distribution the superior vena cava itself may be involved. The history, and the clinical and roentgenographic examination render the diagnosis a comparatively easy matter in these cases.

Axillary compression Metastatic glands from a primary carcinoma of the breast sometimes cause swelling of the upper arm which may be due to pressure on the main venous trunks or to blockage of the lymphatic vessels. Lymph glandular enlargement from other causes rarely results in serious compression of the axillary vein. Aneurysm of the axillary artery (45) axillary hematoma (143) or scar tissue is an occasional cause of venous stasis, but such lesions are obvious on examination.

Swelling of the upper extremity without signs of venous stasis may occur in extensive cellulitis and lymphangitis. Severe injuries of the brachial plexus causing paralysis of the upper extremity may be accompanied by a temporary swelling of the arm. Cerebral monoplegia, syringomyelia, radiculitis, and hysterical edema have been mentioned, but none of these conditions can ever be a source of confusion in diagnosis.

Arteriovenous aneurysms may cause enlargement of the limb with dilatation of the superficial veins the diagnosis can be made from the history and by the presence of a tumor over which there is a thrill and a murmur. If need be, confirmation of the diagnosis is provided by further investigations, such as estimation of the venous content which is raised in this condition.

COURSE AND COMPLICATIONS

The acute symptoms of the syndrome subside after a comparatively short interval, varying from a few days to a few weeks. As the swelling decreases, the collateral circulation becomes more obvious. Complete recovery which implies not only functional recovery but also the disappearance of all pain swelling, and discoloration, and the return to normal of the superficial venous system, has been claimed by many, but a critical study of the cases, combined with a careful follow-up leads one to doubt whether this ever happens however the majority perhaps, ultimately enjoy freedom from symptoms.

So far as it is known, no death has occurred in any case of the Paget Schroetter syndrome. Moore (142) reported a fatal pulmonary embolism which originated from a thrombus in the axillary vein in a woman of 71 years, 4 days after she sustained a fracture of the humerus.

Tommas patient was a man of 45 years who complained of a recent onset of swelling and

discoloration of the right arm. He had been ill at intervals for many years and only a month previously had suffered from an attack of pleurisy. His condition deteriorated and, as his arm was becoming progressively swollen, it was disarticulated at the shoulder. The patient died some days later and autopsy revealed an empyema, multiple thrombosis, pulmonary embolism, and necrosis of part of the arm.

Remijnse reported a somewhat similar happening in a patient of 60 years who died a few weeks after admittance to the hospital. Autopsy revealed thrombosis of most of the large veins, endocarditis, pneumonia and gangrene of the arm.

None of these cases resembled those under consideration and they therefore belong to a different category. So also do the cases with congestive cardiac failure reported by Veal (206) Emmelhorn and Janchar and others. Veal and Hussey (208) found such a high incidence of fatal pulmonary embolism in such cases that they suggested ligation of the subclavian vein.

Nonfatal pulmonary embolism This is of extraordinarily rare occurrence, if indeed it ever occurs. Despite the absence in most cases of any special treatment, embolism has been reported in only 3 patients. Schepelmann (190) removed a thrombus from his patient and 5 weeks later a pulmonary embolism is said to have occurred. It is of significance that the patient, a man of 22 years, suffered from mitral insufficiency and bradycardia, so that two abnormal factors were present—operative trauma and cardiac disease. Roelsen (178) treated 3 patients with heparin and one of the recipients, who previously had an exacerbation of phlebitis following a venogram, developed pulmonary signs believed to be due to infarction. Neff reported embolism in one case but gave no details.

Involvement of the opposite arm. This is also an unusual event, although 6 such cases (2%) have been reported, 2 by Kux (107) and 3 of the remainder by British authors. Firth and Mackay reported the case of a girl of 19 years who developed the condition in the right arm after stirring a pudding 19 months later the left arm became involved although there was no precipitating factor on this side. Selim recorded the case of a man of 36 years in whom the right arm was first affected and 6 weeks later swelling and discoloration appeared in the left. Bellison and Houghton reported the case of a man of 24 years who after a gradual onset in the right arm suddenly experienced swelling and discoloration of his left.

Fig 17 Venous obstruction of the left arm.

Fig 18. Same case as in Figure 17 Infra red venography

Recurrence of symptoms Matas gave an account of a man of 26 years who strained his right arm at work. The patient experienced pain followed by swelling of the arm the swelling subsided later but each time he returned to work the pain and swelling recurred and this happened over the whole period that the patient was observed (4 years) The same writer reported similar exacerbations in another patient observed for 12 years and many others have had the same experience (11 16 61 70 78 79, 84, 101 130 150 171 177 184 215) Veal (206) reported persistent recurrences in 3 patients followed for 6 10 and 22 years, respectively. Recurrences always follow exercise unlike the original attack and are to be attributed to inability of the venous collaterals to respond to the increased flow of blood through the arm rather than to further injury to a vein which has been incompletely occluded by the initial trauma

Persistence of symptoms Swelling discoloration and obvious collateral veins are permanent to some degree. Slight swelling need cause no discomfort to the patient and is easily overlooked. Prominent collateral veins merely signify that the body's compensating mechanism has performed its task more or less efficiently. However pain and discomfort frequently persist and may partially disable the patient. It is possible to segregate arbitrarily only the recurrent symptoms from the persistent, for the former imply a collateral circulation sufficient for all but vigorous work, and the latter, a compensation that

is less efficient. This view is more rational than one visualizing varying degrees of absorption and recanalization of a thrombus (11 84, 159, 171) which has not been proved to exist in all cases.

Many cases have occurred in patients engaged in heavy employment, and as there is a tendency for the symptoms to persist or recur several protracted medicolegal arguments have followed, with the judgment usually in favor of the patient (79 131 150, 171 179) although in Ljunggren's case the etiological importance of trauma was successfully contested.

ETIOLOGY

The most common cause of venous obstruction in the lower extremity is a thrombus but it is doubtful whether such obstruction produces this condition in the upper extremity. It is true that in many of the cases subjected to operation a thrombus has been found in the axillary or subclavian veins. Schepelmann (190) Bazy and others have incised the venous wall and extracted clots, while some surgeons have excised part or the whole of a thrombosed segment. Some of these specimens removed at operation have been examined histologically. For example Roelsen (178) found the vein to be almost completely obliterated, with a narrow central lumen surrounded by granulation tissue containing phagocytes. Other sections showed more recent thrombosis. Lapeyre noted considerable intimal

proliferation, partial rupture of the venous wall, and an organizing thrombus.

Frequently however the surgeon has found no thrombus. In one of Roelsen's cases (177) the subclavian vein was explored but there was no sign of any thrombus a few months later the axillary vein was exposed and it likewise was perfectly normal. The symptoms and signs of venous stasis persisted after the operation. In another case of the same author an exploration of the axillary vein failed to reveal any thrombus although the vessel and its tributaries were dilated. In a third case the subclavian vein appeared quite normal and no thrombus was seen. The subclavian and axillary veins were explored in Ljunggren's case and there was no evidence of thrombus formation. Puhl had a similar experience he operated on 2 patients 25 months and 8 months, respectively after the onset, and found the walls thickened but no thrombosis. Hauge explored the third part of the subclavian vein through a subclavicular approach no thrombus could be felt and the venous walls were of normal appearance. Wulsten (220) found the axillary and brachial veins dilated but there was no intravascular clotting. Others have recorded similar experiences (39, 122, 125, 136, 143, 163).

In reviewing these findings one must be careful to remember that the extent of the exploration is often uncertain from the description of the operation. It is conceivable that a small thrombus was present in an inaccessible part of the vein. The problem is further complicated by such instances as that reported by Wulsten (220) in which palpation revealed a tender tumor in the axilla. It was believed to be a thrombosed vein, yet at operation the vein was normal. Roelsen (178) suggests that certain clinical differences exist between the thrombotic and nonthrombotic cases. In the former group he thinks that the precipitating trauma is negligible and that the patient frequently has a mild elevation of temperature. However there are many exceptions to this and such a partition appears to be wrong.

Whether thrombus formation be of primary or secondary importance its cause must be sought. Winterstein and Stover and Herrel both reported cases of polycythemia presenting with thrombosis of the axillary and subclavian veins. The latter reviewed the literature and found that this was such a rare association that only one similar case had been reported (a patient of Parkes Weber). In no other case has a full examination of the blood, either chemical or cytological, revealed any predisposing cause whatever and this possibility may be dismissed.

A few authors believe that slowing of the blood stream is an important factor. Lowenstein and Schwindt considered that the presence of valves within the veins and fixation of the venous wall to the costocoracoid ligament, the clavicle and the rib, retarded the rate of blood flow. As pointed out previously cardiac failure may be complicated by axillary and subclavian thrombosis, and Ruge considered that such could be regarded as an early manifestation of circulatory failure. Humphry described such a complication in the terminal stage of a debilitating illness in a girl of 19 years and in a man of 45 who died of phthisis, the right upper extremity having for some days been oedematous, and the superficial veins of the arm and shoulder distended, we found the subclavian vein, near its junction with the internal jugular blocked up by a tough brown clot, which was adherent to the interior of the vein. Blumer described a similar case and reviewed several others from the literature. These cases are seemingly terminal events and differ fundamentally from those considered here in which the patients are healthy active people, in whom any general blood stream stasis may be at once excluded.

Most attention has centered around the possibility of an abnormal venous wall which acts as a focal point for thrombus formation and a few believe that infection is the cause. Wilson recalled the rarity with which phlebitis occurs in the upper extremity in typhoid fever but stressed the importance of syphilis. In support he quoted Marcel Gangard who reported 2 cases of subclavian thrombosis, and Muscher whose patient developed brachial thrombosis. All 3 patients were syphilitic. Gould and Patey (70) Sloan and Roberts, Leocadio and Huard (88) have reported thrombosis of the upper extremity complicating an aneurysm of the aorta, while others have had patients with positive Wassermann reactions but without aneurysmal formation (45, 64, 141, 181, 201, 222). Paget and Lenche prescribed anti-syphilitic treatment in their cases although there was no evidence of the infection. Humphry was the first to report the condition in tuberculous patients. Aldrich collected 9 cases from the literature and added one case of his own. Other cases have since been described (217). This occasional association of specific infections with subclavian and axillary thrombosis provides no significant information on the etiology of the Paget-Schroetter syndrome.

The theory of nonspecific infection was advanced by and received considerable support from, French authors (2, 30, 97, 115, 118, 183).

Lecene considered that the alleged trauma was usually too trivial, while Lenormant (117) and Ducuing suggested that the role of injury was merely to activate a subclinical infection. In support of an infective origin is the unquestionable fact that some of the patients have fever, a few have displayed leucocytosis and the blood sedimentation rate may be elevated. Forster's patient and one of Sampson's (184) suffered from chronic sinusitis in addition to the axillary thrombosis; other cases also have followed an upper respiratory tract infection (43 67 72 95 106).

Several histological and bacteriological examinations have been cited as favorable evidence for infection. Huard and Lenormant (89) reported chronic inflammation of the walls of the vessels, most marked around the vasa vasorum. Chifoliau and Follisau noted many leucocytes in the venous wall, and microscopic examination of the resected portion in Herbrand's case also suggested latent sepsis. In Lenormant and Mondor's specimen (118) it was said that it was actually possible to see staphylococci about the vasa vasorum. Patel and Morel Fabo resected 12 cm. of a thrombosed segment and histological examination revealed recent thrombosis with partial organization and moderate infiltration of the vessel wall with leucocytes, while staphylococci were obtained from a culture. Chifoliau and Follisau cultured the staphylococcus, Grimaud and Dantlo the streptococcus viridans, and Lenormant and Mondor (118) obtained a very feeble growth of the staphylococcus albus and the colon bacillus. Broca reported that the axilla appeared inflamed at operation. Biehl found a lymph gland in such close connection with the venous walls that it had to be removed by sharp dissection, and examination of the gland later revealed a subacute non-specific inflammation. Both Biehl and Rosenthal believed that the close proximity of these glands to the axillary vein provided an easy opportunity for direct transmission of infection. Girard (66) and Wulsten (220) observed patients with septic hands, but with mild infection on the same side as the lesion.

However the evidence is against infection in any but the occasional case. Most of the patients show no systemic reaction at all; the temperature, pulse, white blood cell count, and sedimentation rate are normal. This disproportion between the local condition and constitutional disturbance is one of the remarkable features of the syndrome. Moreover specimens obtained at operation have on many occasions proved sterile. Axillary thrombosis is a rare condition; yet axillary adenitis secondary to infections of the hand is common.

Fig. 19. Veal and McFetridge (209) believed the axillary vein was constricted against the subscapularis muscle with stretching of the vein just proximal to the point of constriction. (*Archives of Surgery*)

Most authors believe that trauma is responsible; the intima is damaged and a thrombus forms. Although the condition has followed a direct injury varying from a mild blow on the arm or shoulder to severe crush injuries of the chest (26 40 44, 81 101 107 126 154 155 158 171 218) it has much more often been induced indirectly. The onset has frequently occurred at the time of or soon after lifting a heavy weight (Table I). On the other hand, Stabins reported an example in a man working with his arms above his head installing an air plane motor. Lenormant and Mondor (118), a painter at work on a ceiling. French, a patient who was in the habit of reaching for objects. Roelsen (178) a man who lifted rolls of cloth from shelves. Gould and Patey (70) a clerk who considered his swollen arm to be a sequel to the insertion of 18 screws into a wall above his head, and another case which was attributed to the placing of jars on a high shelf, and De Bakay, Ochsner and Smith believed one of their cases was caused by the patient's sawing a tree with his arm above his head. Hartmann

Fig. 20. Wright (119) considered that the vein was damaged as it passed posterior to the pectoralis minor muscle beneath the coracoid process. (*American Heart Journal*.)

described an onset which followed an extra strain to push a bed past an obstacle. McGoogan and Simmons and O'Regan, instances due to strenuous pulling efforts. It may follow such sustained movements as washing clothes (179, 207) or dishes (184), swinging a sledge hammer (216) or a 25 pound book (171), pitching soya beans (132) or stirring a heavy pudding (61), digging a hole with a crow bar (86), beating time with a baton (43), prolonged carving (56), pushing and pulling heavy silk measuring machines (102), overtime in iron smith work (152) or bell ringing (162). It has been reported in tennis and squash players (23, 184, 201), golfers (70), baseball players (84, 101, 130, 184), rowers (200, 215), boxers (163), swimmers (3), basket ball players (158, 178) and those engaged in gymnastics (12, 36, 59, 98, 139, 149, 177). It has been noted in drunkards (33, 143, 215) and in epileptics (106, 216). It may follow as trivial an episode as putting an arm into an overcoat sleeve (128). There may be nothing at all to account for its onset, and no fewer than 39 persons (13% of the number in which the onset is described) awoke with symptoms of the disease (Table I).

Attempts have been made to analyze the movements of the upper extremity and to isolate some specific maneuver common to every case. For example Taylor believed adduction at the shoulder to be important. Veal and McFetridge (209) and Neij adduction and McGoogan and Simmons, abduction and external rotation. Some believe it is a minimal effort (64, 116) others that it is of undue vigor (39, 150).

Several anatomical investigations have been conducted with the object of locating a vulnerable site in the course of the axillary and subclavian veins, and as a result each part of these veins has been regarded, at sometime as the part at fault.

Veal and McFetridge (209) put forward the view based largely on venographic studies, that the axillary vein might be damaged by action of the head of the humerus through the subscapularis muscle. This theory has received little support (Fig. 19).

Wright believed the vein to undergo 'tension, stretching, and pinching' as it passed posteriorly to the pectoralis minor and just beneath the coracoid process. The vessel is normally well protected, but in hyperabduction it is stretched around and beneath this process. By the same action the pectoralis minor is drawn tight, and it is suggested that this double action might injure the axillary vein (Fig. 20).

Willan considered the lesion to be in the first part of the axillary vein, that is, in the region between the outer border of the first rib and the medial edge of the pectoralis minor. He thought the vein somehow suffered damage against the rib border during vigorous exercise and that the intima of the vessel was roughened, which determined the onset of thrombosis.

Lowenstein concentrated his attention on that part of the vein lying between the rib and the clavicle. He pointed out that the inferior border of the costocoracoid ligament is sharp, strong and crescentic, and is strengthened by the tendinous fibers in the subclavius muscle. The inferior border of this muscle is fibrotendinous from its costal origin for at least 5 or 6 cm. laterally and fibrous bands may extend to the coracoid process. As the subclavius muscle and costocoracoid ligament follow the course of the clavicle laterally and posteriorly they cross the vein. When the arm is abducted to the level of the shoulder the subclavius muscle and costocoracoid membrane are put on the stretch and the sharp firm lower border of the costocoracoid ligament exerts considerable pressure on the superior surface of the vein. Lowenstein found that the maximum pressure was brought to bear when the arm was in extreme

abduction especially when rotated laterally the indentation, he thought, might be increased by the downward pull of the pectoralis minor. Gould and Patey (70) injected plaster of Paris into the axillary veins of postmortem subjects, the arms of which were held in fixed abduction. In one instance a shallow groove was obtained in the cast corresponding to the position of the costocoracoid ligament, while in 2 other cases a deep broad groove from pressure of the subclavius was seen. Lowenstein also noted that as the axillary vein crossed the shelving upper surface of the first rib it was provided with a valve. Gould and Patey (70) found this to be a fairly constant structure and suggested that its rupture a consequence of pressure was the fundamental pathological lesion. Hughes however found that with abduction of the arm the clavipectoral fascia which stretches between the costocoracoid ligament and the pectoralis minor pulled the former ligament away from the vein he was unable to detect any significant compression of the vein between the subclavius muscle (and the costocoracoid ligament) and the first rib.

Falconer and Weddell believed that the subclavian vein was compressed between the clavicle and the rib. They demonstrated that backward bracing of the shoulders sometimes led to distention of the superficial veins of the limb with opening up of the collateral venous channels across the pectoral region to the veins of the neck. The offending movements were, firstly and the more important, backward and downward bracing of the shoulders, and, secondly hyperextension of the neck, which probably also narrows the angle between the first rib and the clavicle. In this maneuver the scalene muscles may play the part of an elevator of the anterior end of the first rib (Fig. 21). Judovitch Bates, and Drayton favored this theory and referred to 2 cases in which the axillary vein was found to be dilated to one and a half times its normal size on the lateral side of the first rib. Others have also believed that in certain actions the clavicle compressed the subclavian vein against the rib (9, 200). However Hughes did not support this view for he noted that as the clavicle approached the rib the subclavian vein slipped forward under the clavicle and away from the maximum pressure zone. Telford and Mottershead found that in normal subjects it was necessary to sever the intra-articular disc in order to approximate the rib and clavicle, although such compression might be important if the costoclavicular interval was already narrowed. In this connection it is of interest to note that cervical ribs are rarely found in cases of venous ob-

Fig. 21 Falconer and Weddell (54) thought that the vein might be compressed between the rib and clavicle (a) particularly in the presence of an abnormal first rib (b) (*Lancet* Lond.)

struction of the upper extremity although their presence has often been suspected. Hermodsson observed a patient with a cervical rib and Mc Googan and Simmons noted the suggestion of a cervical rib in their patient. In Pinelli's case the abnormality existed on both sides and was more prominent on the side of the venous stasis, while Andersson mentions a patient presenting a cervical rib syndrome with occasional swelling and signs of mild venous stasis in both arms.

Loehr (125) suggested that there was a 'relative' obstruction at the hiatus between the rib and the clavicle. Nearly all the blood from the upper extremity must pass through this narrow space in order to reach the caval circulation. Loehr considered heavy exercise caused a constriction at this point, which was aggravated by the increased thoracic pressure. The subclavian vein surrounded by strong fascia is prevented from overexpanding while the axillary vein which lies free is acutely overdistended a vein so damaged does not recover quickly but tends to remain dilated for several days and furthermore, it is more easily distended a second time and subsequently Loehr visualizes the resulting edema

Fig. 22. The relation of the subclavian vein, subclavian artery, and adjacent structures. Sampson Saunders, and Capp (85) drew attention to the narrow interval between the subclavian vein and medial border of the scalenus anterior (*America Heart Journal*)

compressing the vein and so causing a vicious circle of changes.

Sampson Saunders, and Capp (185) pointed out that as the subclavian vein lies between the scalenus anterior and the clavicle, it occupies a very narrow space, which in the adult is scarcely 1.5 cm. wide. They considered that this part of the subclavian vein might easily be compressed but that vascular occlusion was also partly a result of the veins becoming stretched over the rib. These authors suggested that high, wide first ribs and horizontal, backwardly directed clavicles were important predisposing factors to the development of venous thrombosis and were constant features in such patients (Fig. 22).

However these theories so far considered seem inadequate. No typical movement or combination of movements preceded the onset of the condition which indeed, may follow a period of relative inactivity. Surgical exploration has frequently disclosed no sign of a thrombus at all, yet there is every indication that the obstruction is permanent and that the degree of disability depends on the inefficiency of the collateral circulation. It is remarkable that no definite instance of embolism has been reported, a movement of the shoulder girdle which is sufficient to traumatize the vein and cause a thrombus should also be capable of detaching part or all of that thrombus.

Hughes has suggested that a preavenous phrenic nerve might obstruct a subclavian vein. The

phrenic nerve possesses considerable tensile strength even a tiny accessory phrenic nerve may damage the subclavian vein when it is avulsed. Usually the phrenic nerve passes posteriorly to the subclavian vein, but it may pass anteriorly (55 87 188). This preavenous phrenic nerve occupies a more lateral position than a normal nerve. It curves forward around the tendon of the scalenus anterior and after crossing the subclavian vein immediately turns posteriorly to enter the superior mediastinum (Fig. 23). The nerve bears an intimate relation to the vein and may even pass through its wall (87 167 188). With inspiration, contraction of the scalenus anterior and elevation of the first rib accentuate the abnormal angulation of the preavenous phrenic nerve as a result of the increased tension on the nerve caused by descent of the diaphragm there is a strong tendency for the subclavian vein to be nipped against the tendon of the scalenus anterior by the nerve. As the right phrenic nerve takes a shorter and more direct course to the diaphragm, and since the excursions of the diaphragm and the first rib are greater on the right side and in males (41) the characteristics of incidence receive an explanation. Such a venous constriction could occur in the absence of any effort, the deeper breathing associated with sleep might precipitate it, as might unusual extension of the neck. Subclavian and axillary thrombosis may or may not occur as a complication, but thrombosis proximal to the obstruction (and hence embolism) is rendered improbable or impossible by the site of obstruction near the junction of the subclavian and internal jugular veins. Hovelacque and his colleagues have suggested that a preavenous nerve may cause injury to the external jugular vein. Hughes submits that it should be considered as a cause of venous obstruction in the upper extremity (Fig. 24).

Other extravascular structures have been described as obstructing the vein. Such observations must be accepted cautiously as any unyielding tissue in close relation to a distended vein might give the impression that it is constricting the vessel. Wulsten (220) divided an axillary arch as it passed between the latissimus dorsi and the pectoralis major. Fascial strands in contact with the vein were found by Ljunggren, Wagner and Neff. Loehr (125) removed a group of glands from his patient and believed they were pressing on the axillary vein. Demel and Spallizer interpreted a venogram as "apical adhesions indenting the subclavian vein". One of Heinecke's patients showed excessive callous formation after a fractured clavicle. Hauge noticed a small osteoma of

the clavicle in one case and Clifton reported venous stasis of the upper limb due in part to an enlarged subclavius muscle and in part to a traumatic posterior subluxation of the clavicle. Rosenthal and Pellet (196 157) believed that inco-ordinated muscular action could detach venules from the main veins and so cause the intraluminal lesion necessary to initiate thrombosis. Lahaussouss suggested that a sudden muscular contraction resulted in such an abrupt rise in the intravenous pressure that the vessel wall was ruptured. Moure and Martin (143) at an operation performed 7 weeks after the onset found no thrombus, but the inner edge of the coracobrachialis muscle showed signs of considerable bruising and it was thought that a hematoma had compressed the vein. Cadenat and Veal (206) considered that forced expiration could in certain circumstances, damage the vessel. Pavlovsky suggested that the injury was sustained at the point where the subscapular and the circumflex humeral vessels drain into the axillary vein at this point the vein widens and presents a region of comparative stasis.

The role of spasm of the vessels in producing the clinical features of this condition is uncertain. There is some evidence that venospasm exists in many cases. Lapeyre and Cottalorda consider that venospasm provides the only reasonable explanation for the rapid onset and the rapid recovery that might occur. The latter believed the operative findings for vasomotor lesions and were caused by a focus of irritation in the perivessel tissues or actually within the lumen of the vessel. It was an upset in the vasomotor equilibrium due to this focus which caused the edema rather than any obstruction of the vein. Based on these considerations Cottalorda and others have excised a portion of the vein or have performed a perivascular sympathectomy. Instead of removal of this supposed focus of irritation or interruption of the sympathetic nerves by operative means, the assumed pathway of impulses may be blocked centrally by injecting novocain. This brachial sympathetic block can have no influence over the venous obstruction if it is due to thrombosis or may have a favorable effect on the peripheral circulation (147 207) but its chief value seems to result from the dilatation of the collateral vessels which it causes.

TREATMENT

So few cases are seen in any one clinic that it is not surprising that there is no unanimity of opinion as to the most effective treatment. The

Fig 23 A pre-venous phrenic nerve. The pre-venous nerve occupies a more lateral position than the normal structure. It courses forward to cross the vein and then turns sharply backward to enter the mediastinum. It lies lateral to the external jugular vein. On inspiration the contraction of the scalenus anterior muscle and the elevation of the first rib increase the angulation of the nerve while the descent of the diaphragm tightens the tendon of the scalenus anterior. (This specimen is now in the Hunterian Museum of the Royal College of Surgeons of England.)

problem is complicated by the variation in the course of the illness in the patients that receive no special treatment some making an apparently complete recovery in a short space of time, others having a protracted course and never regaining normal function of that limb.

No special treatment. In most cases treatment has been symptomatic without resort to any special measures. The patient is usually ordered to bed with the arm elevated. Some believe that active movements are indicated from the outset because it is thought that exercise promotes emptying of the lymphatics and veins, improves the circulation and discourages propagation of the thrombus. There certainly appears to be no danger of dislodging a thrombus (178 207, 208) Heat

Fig. 24a

Fig. 24b

(101) ice packs (11), vasodilators (183) elastic bandages (104) and other ancillary measures have been used.

Anticoagulants. In recent years anticoagulants have been administered (6, 21 90, 98, 114 139, 178) but the cases are too few as yet to permit evaluation of such treatment. Theoretically these drugs should retard or prevent the propagation of a thrombus and so leave the patient a maximum number of tributaries which are all concerned in the establishment of a collateral circulation.

Heparin has an advantage over dicumarol in that the anticoagulant effect can be rapidly produced and rapidly stopped but the latter is less expensive and can be given orally. As dicumarol must be allowed at least 36 hours to produce its effect, it is the author's practice in similar circumstances to combine the drugs initially but to discontinue the administration of heparin after 36 hours.

Heparin (Ikquemia) is supplied in 5 c.c. vials containing 1,000 Toronto units per cubic centimeter. The contents of a vial are drawn into a syringe containing a little normal saline solution, and 5,000 units are given intravenously at 4-hour intervals for 36 hours.

Dicumarin (dicumarin-organon, dispensed in tablets of 50 mgm. each) is started by mouth on admission in a dose of 300 mgm. On the second

day it is reduced to 200 mgm. and subsequently a daily maintenance dose of from 50 to 100 mgm. is given with the object of keeping the prothrombin time between 20 and 30 per cent for from 10 to 14 days.

Paravertebral cervical sympathectic block. Ochsner and De Bakcy and Rieder were the first to recognize the value of injecting the stellate ganglion and the upper two or three thoracic ganglia with 1 per cent novocain in this condition, and the former subsequently reported 4 cases in which the patients were so treated. Others have also obtained good results. Bruce noted a dramatic improvement after a single injection in his case, but Ochsner and De Bakcy found that two or three injections may be necessary.

The author uses a posterior approach, with the patient either sitting and inclined forward, or lying prone. Three skin wheals are raised two and a half finger breadths lateral to the spinous processes of the seventh cervical and first and second thoracic vertebrae. A 10 cm. needle is inserted at right angles to the skin surface as far as the rib, under which it is maneuvered. It is inclined medially 25 degrees and pushed another 2 or 3 cm. From 5 to 10 c.c. of 1 per cent novocain are slowly injected at each point.

A sympathetic block should certainly be carried out before any other surgical procedure is contemplated.

Fig. 24c

Fig. 24 Further examples of pre-venous phrenic nerves (Hovelacque, Monod, Eyraud and Beuzart (87)) (*Annales d'Anatomie Pathologique*.)

Operation Uncertainty in the etiology and pathology is reflected in the uncertainty with which the surgeon has approached this problem. Considerable weight of opinion is against a surgical attack. An exploration of the axillary and subclavian veins is a formidable procedure and each vessel that is divided during the operation no matter how small it be is a handicap to the collateral circulation.

Attempts have been made to formulate indications for surgical intervention such as rapid increase in the swelling (14 39 88) persistence of swelling despite adequate rest (14 39 122 178) and recurrence on exercise (97). But in most cases the surgeon has been influenced by the belief that he might find and relieve an obstruction or eradicate or interrupt a focus of irritation.

Phlebotomy and removal of clot This has been performed on a few occasions (14 17 80 93 190). Whether a thrombus be secondary to an extravascular obstruction or an intimal lesion its removal, partial or complete will facilitate the establishment of the collateral circulation. How ever anticoagulant therapy commenced soon after the onset should obviate the need of such a procedure, while organization of the clot quickly renders chances of its success remote.

Schoepelmann (190) was the first to report an operation in the treatment of this condition and he performed a phlebotomy with removal of the clots. Bazy reported rapid recovery of his patient following a similar procedure 9 days after the onset. Biehl and Henningsen were not able to extract all the clot from the veins of their patients.

Exploration with or without venolysis To dissect and remove an extravascular obstruction must be the main incentive to the surgeon. Yet the results of exploration have not been particularly encouraging. This is not surprising the axillary vein is not difficult to expose but the subclavian vein is relatively inaccessible indeed it is doubtful whether the first and second parts of the latter vein have ever been satisfactorily explored in this condition.

Ljunggren, Loehr and Puhl reported good results following exploration of the axillary vein and the removal of constricting bands of fascia. Wulsten (220) believed that the vein was compressed by a thickened Langer's arch which he removed. Zachau found the subclavian vein constricted at the level of the first rib and the patient improved after venolysis. Moure and Martin (143) operating 2 months after a recurrence found bruising of the inner border of the coracobrachialis muscle, and following evacuation of a serous exudate the patient was able to return to work in 3

weeks. Zinniger found a thrombus within the axillary vein of Mont Reid a case and closed the wound without drainage following which the patient recovered rapidly (168). Fievez and Broca had similar experiences, but others have been less successful.

Scalenotomy Division of the scalenus anterior widens the costoclavicular interval and hence removes a possible extravascular obstruction. McLaughlin and Popma and Ney are the only authors to report such an operation and both obtained good results.

Excision of a venous segment This operation is designed to eradicate a focus of irritation which is said to exist in the vein or in the perivenous tissues and which is responsible for impulses exerting a baneful effect locally and more peripherally. Many satisfactory results have been attributed to this procedure, but equally as good progress has been made by those receiving no

HUGHES VENOUS OBSTRUCTION IN THE UPPER EXTREMITY

125

20. Abnormality of the circulating blood in section of the venous wall and general circulatory stasis are of no significance in the causation of this condition.

21. Injury to the vein resulting in thrombus formation on a roughened intima is the most popular conception. Each part of the axillary and subclavian veins has at some time, been incriminated.

22. An extravascular obstruction is believed by the author to be the probable cause, with thrombosis a common sequel. A preavenous phrenic nerve may be the extravascular structure responsible.

23. Venospasm may play a role in the production of the clinical features, but it is difficult to attribute to it any etiological significance.

24. Anticoagulants should be administered as soon as possible after the onset. A paravertebral sympathetic block which assists the developing collateral circulation is advisable. If thrombus formation has already occurred operative success cannot be anticipated if this complication has not resulted the collateral circulation should be adequate to compensate for the obstruction. Hence surgical interference is probably not justified.

I am indebted to Professor F. Wood Jones for his direction and kind criticisms, and to those physicians and surgeons who have so generously allowed me to study their cases. I wish to express my thanks to Professor E. D. Telford, Professor J. R. Learmonth, Mr. D. H. Patey, Professor A. M. Boyd and Mr. S. Mortenson for much helpful advice. The technical assistance of Dr. D. Tompaert and Mr. Beckwith has facilitated the work.

EYE

Research in Orthoptics. F. ELIZABETH JACKSON
Am J Ophth., 1948 31 805

The author points out that certain essentials are necessary to obtain a truer perspective of the whole field of binocular training and of the treatment of strabismus. In order to benefit from research in orthoptics the terminology used in orthoptics should be classified on the basis of ophthalmic technology. The evaluation of results should be standardized, and sensory variable factors should be eliminated, and sensory data should be collected and analyzed to stimulate and direct further study of the etiology, manifestations and over-all treatment of strabismus. In addition some knowledge of the basic principles of child psychology would be helpful so that a better understanding could be acquired of what can be expected of a child at various age levels.

Time and effort involved in research in orthoptics can be minimized by keeping records of the diagnosis, treatment and the follow-up data on all cases and by keeping an abstract file of current publications. The results of research in orthoptics can be given as a statistical survey a comparison study and individual case reports. JOSEPH ZUCKERMAN M.D.

Pathogenesis of Myopia: A New Classification, 1948, 39 273
FREDERICK C. STANBURY Arch. Ophth., Chic.

The various theories of myopia are critically and historically reviewed in a comprehensive and scholarly manner. After careful consideration of the various theories, the author proposes a classification of myopia into (1) primary or physiologic myopia and (2) secondary or pathologic myopia.

The concept of primary myopia is based upon the view that refractive errors are biologic variations and that people are hypermetropic or myopic by the same chance variations as people are short or tall. It includes myopia of both high and low degrees with the vision correctable to normal standards and the eye healthy.

Secondary myopia is a disease of the eye the cause of which has not been determined but which

process which it surrounds. The most formidable possibility is that in the depths of the warren the deep lobe is adherent to the jugular vein near its bulb. For this reason more than for any other the operator can consider that the exacting operation is virtually completed when he is convinced that the deep lobe consists entirely of normal parotid tissue. After the deep lobes including undoubted rabbit warrens *in situ* are left a salivary fistula following superficial lobectomy is often conspicuous by its absence.

The experience of the author in dissecting Stenson's duct in the living is at variance with what is depicted in works on anatomy. In over 80 per cent of the cases Stenson's duct is a rounded structure no larger than a fine hypodermic needle.

In a review of the results of parotidectomy by the author 45 of 54 patients were treated for tumors. In 17 cases the tumor was a recurrent one. In 1 case it had recurred 4 times, and a number of patients had received radiotherapy without benefit.

As for the integrity of the seventh nerve in 2 patients no attempt was made to preserve it, because in one the nerve had been cut at a previous operation performed elsewhere, and in the other the anatomy of the nerve was so extensive and fragile that the anatomy of the region was confused. Of the remaining patients for varying periods up to a year. Only 5 of these showed signs of facial muscular weakness after a year but none of them were seriously inconvenienced by the integrity of the seventh nerve cannot be guaranteed for several months.

Regarding the pure anatomy of the facial nerves as far as the author was able to ascertain Barry Anson professor of anatomy, Northwestern University of Chicago stands alone among English speaking anatomists in teaching that the parotid gland is a bilobed structure with the facial nerve running between the lobes. The author supports this contention through his experience in the surgical treatment of the parotid gland.

SURGERY OF THE HEAD AND NECK

HEAD

Surgical Anatomy of the Parotid Gland HAMILTON
BAILEY *Br J M J* 1948, 245.

This is an excellent presentation on the surgical anatomy of the parotid gland with a review of the results obtained in 77 cases in which parotidectomy was performed. In 54 cases superficial lobectomy or total parotidectomy was performed and in the remainder extracapsular resection of a tumor was carried out.

There are considerable variations in the disposition of the facial nerve within the parotid gland, and for practical purposes it was stated that more often than not the facial nerve lies between a comparatively large superficial lobe and a variably sized deep lobe, the two being connected by an isthmus (see fig 1). It is on this anatomical concept that operations of superficial lobectomy and complete parotidectomy

Fig. 1. Diagrammatic conception of a coronal section through the parotid gland, showing the branches of the facial nerve sandwiched between the superficial and deep lobes.

Fig. 2.

are rendered practical. Consequently a description of the surgical anatomy of the parotid gland is presented.

The facial nerve emerges from the base of the skull at the stylomastoid foramen. After a course of approximately 0.5 inch (1.25 cm.) it appears to plunge into the deep aspect of the gland a little below its middle. Actually it comes to lie in a groove on the under surface of the superficial lobe. For example the main trunk of the nerve can be separated by blunt dissection from the mobilized gland. The main nerve trunk approaches the parotid isthmus from behind, and on reaching the isthmus divides into an upper temporofacial branch which passes above the isthmus and a lower cervicofacial branch which passes below it (Fig. 3). Because of the relatively small size of the deep lobe, only the subdivisions of the nerve—for instance the *pes anserinus*—rest between the superficial lobe and the masseter muscle. Particularly from a surgical point of view the temporofacial division which is often the larger of the two divisions, is the most important.

In a number of instances, after the two primary divisions of the nerve have embraced the isthmus they are connected at a varying distance in front of the isthmus by one or more anastomotic twigs (Fig. 3). No doubt this accounts for some cases of unexpected late recovery of partial facial paralysis following parotidectomy.

The isthmus is variable. Sometimes it is relatively broad even so the primary divisions of the facial nerve seem always to embrace it.

The superficial lobe also varies in size and shape. Large superficial lobes often extend as much as 2 inches (5 cm.) into the neck (Fig. 3). On scores of occasions in the course of excision of adherent tuberculous cervical nodes situated in the upper third of the neck it was necessary to resect a portion of the cervical prolongation of the parotid gland.

The deep lobe may belong to one of two categories, the "knob" and the "rabbit warren". In approximately 40 per cent of the cases with the knob type the deep lobe is relatively small, ovoid in shape and overlies the base of the condylar process (Fig. 4). It has been argued that if the tumor is removed satisfactorily by superficial lobectomy it is inconsistent with radical surgery to leave behind a piece of parotid gland (the deep lobe) even if this knob is presumed to contain normal tissue. However it is oftentimes uncertain whether the deep lobe is strictly of the knob variety. In the rabbit warren type of case there is a prolongation with the deep surface of the deep lobe that plunges behind the posterior border of the mandible (Fig. 5) toward the styloid

SURGERY OF THE HEAD AND NECK

131

same pressure movements may be observed in all arteries of visible organisms and there are no other movements performed by the arteries. The pressure movements in question are directly due to cardiac systole and diastole and arise as the result of periodical changes in arterial pressure. Notwithstanding that the arteries do not perform peristaltic movements they are because of their structure able to give an impetus to the onflow of simple mechanical laws. The arterial pressure movements are actually in the circulation on the basis of simple mechanical laws. The arterial pressure does not depend on arterial dilatation and contraction. The facts mentioned about arterial pressure movements together with the complete immobility of the present lead to the conviction of the pulse. A false pulse is met with in the artificial product caused by pressure theory on the cause of the pulse. The blood stream in its first phase originates at the genesis of life and continues to flow on uninterruptedly, receiving a rhythmic stimulus due to cardiac systole.

Summing up all of his results in brief the author states that the arterial pulse as well as the venous "pulse" is a passive pulse produced by a rhythmic throbbing due to eyeball pressure. The blood stream in the vein is uniform circulating without any oscillations because of pressure so that there is no difference between diastolic and systolic pressure. Because of a fundamental error of Bailliant's method pressure pulse has been identified with spontaneous pulse. A spontaneous pulse in the retinal artery comes nearer the truth. It can be observed in 80 per cent of quite healthy individuals who are not suffering from circulatory disturbances. The result turns out to be different in cases of rapid pulse. This depends on the rhythmic onward thrust of a section of the artery due to cardiac systole in the same way as the pulse in other arteries. However only adequate experience in the observation of question of pressure in the afford an answer to the question of pressure in the retinal vascular system. Unfortunately such experience is humanly impossible.

The methods of investigating pressure in the brain cannot be adopted for the measurement of pressure in the retinal blood vessels. The pressure on the eyeball creates entirely different physiological conditions so that there is no analogy between the two methods. Considering that the difference between arterial pulse is hardly perceptible by Bailliant and between systolic and diastolic pressure is practically nil and is therefore not capable of being measured. If conditions were such as suggested by Bailliant and retinal artery would necessarily be more distinct than at once and would necessarily be more distinct than the arterial pulse in which this proportion amounts to 0.6.

By Bailliant's method we are able to investigate the height of retinal venous pressure in so far as the vein does not present independent "pulsation" i.e. pulsation occurring already without pressure. Bailliant's

method does not enable us to estimate pressure in the central retinal artery but we can thereby determine the approximate pressure existing in the ophthalmic artery. In consideration that the central retinal artery is considerably narrower than the ophthalmic artery the pressure in it must necessarily be considerably lower which, however cannot be determined even approximately.

EARL H. MERR, M.D.

EAR

Minimal Shock Pulse Trauma to the Cochlea—Acute and Chronic. H. B. FRIEDMAN *Laryngoscope* 1946 55: 466.

The author presents his views following a study of the literature on blast trauma to the middle and inner ear. Many reports are cited which indicate that damage to the inner ear as the result of industrial noises, gun shots and other battle noises, often with little or no evidence of injury to the middle ear may occur. His purpose was to perform experiments in which the cochlea was damaged by an explosive sound but no damage was done to the rabbit. The experimental animal used was the rabbit. The animal was exposed and perforated to provide a view of the middle ear structures and an ear speculum was inserted through the perforation through which by reflected light, the tensor tympani muscle was observed. The threshold for acoustic contraction of the tensor tympani was observed by presenting pure tones generated by a Western Electric 6 B audiometer through a loud speaker next to the ear. The intensity at each frequency needed to produce a just visible contraction of the tensor tympani when the tone was suddenly turned on and off was recorded. Average readings were taken as the threshold response for the ear. The opposite ear in all acute experiments was destroyed by en-

tering the bulla and knocking off the promontory. In some chronic experiments a threshold of a few minutes was again determined at intervals of a few minutes to several hours. The shock pulse was developed by a .32 caliber blank cartridge fired from the starting pistol at a distance of 1 to 2 feet from the animal. A group of animals also, after exposure to the pistol shot, were allowed to live from periods of 3 to 12 weeks. After the experiments in fixing the bones were immediately sectioned serially and ultimately the material obtained in these experiments the author found the following:

1. Small changes in auditory function in these animals as tested by little histologic evidence in the cochlea of the cochlea.
2. Profound loss of auditory function as tested seemed out of proportion with the limited histologic damage of the cochlea.

may be a chronic low grade choroiditis. It is associated with fundus lesions such as staphyloma, myopic crescent, choroidal atrophy degeneration and hemorrhage retinal atrophy and pathologic changes in the vitreous. The main factor in differential diagnosis of the two types is the appearance of the fundus. Proper classification is of great value clinically in therapy in prognosis and will prevent the waste of many useful citizens as "myopic cripplers."

FRANK W. NEWELL, M.D.

Ligament of Lockwood in Relation to Surgery of the Inferior Oblique and Inferior Rectus Muscles. WALTER H. FINE. *Arch. Ophthalm. Chic.* 94:3 39-37.

The author presents an anatomical study of the suspensory ligament of the eye and its importance in the management of abnormalities of the inferior oblique and inferior rectus muscles.

Excellent reasons why surgery of the inferior oblique muscle should be done at its insertion rather than its origin are indicated. Fusion of the sheaths of the two muscles is very variable and surgery at origin is therefore also unreliable and variable.

In operating upon the insertion of the inferior oblique muscle the insertion of the muscle sheath is also of great importance and severance of the sheath is essential for good results. The recession and reattachment of the muscle should be in line of action of the muscle. The illustrations are clear and explanatory.

EARL H. MEER, M.D.

Effect of Roentgen Therapy on Experimental Ocular Vaccinia in Nonimmune and in Partially Immune Rabbits. GRO. GE. T. HALL, L. CHARLES H. REID, J. M. YWELL, LITTLE J. W. W. BLANKIN. *Arch. Ophthalm. Chic.* 94:3 39-35.

The effect of direct irradiation at different stages of ocular vaccinia in nonimmune and partially immune rabbits was investigated. Rabbit eyes were irradiated in 24 to 48 hours after inoculation with calf lymph virus at varying intervals after vesiculation commenced and at the height of the reaction.

Irradiation was of value as a means of hastening regression of the acute lesion and decreasing residual corneal opacities. This latter observation was not borne out by measurement of the transmission of light with a photoelectric technique. Additional animals were partially immunized by primary inoculation of the skin and 72 hours later the corneas were inoculated. At varying intervals thereafter the corneas were treated with roentgen therapy. Results were similar to those observed in nonimmune animals although in general, the disease was less severe and the residual opacities less. Partial immunity without irradiation also protected against residual corneal opacities.

The authors discuss the possible causes of the discrepancy between simple clinical observation of the cornea and the statistical comparison of objective measurements of light transmission with a photoelectric colorimeter.

FRANK W. NEWELL, M.D.

Experimental Studies of Ocular Tuberculosis: Failure of Penicillin to Affect the Course of Experimental Ocular Tuberculosis. JOHN D. KENNEDY, ALLAN C. WOODS, JOHN BUTCHLEY MORGAN, BERTHONG, AND EARL L. BURKE. *Arch. Ophthalm. Chic.* 1943, 30: 261.

The anterior chambers of rabbits were inoculated with a culture of virulent human type of tubercle bacilli. Five weeks later animals with similar lesions were divided into treated and control groups. The treated rabbits received 50,000 units of penicillin G subcutaneously four times daily for 45 days. The course of the ocular tuberculosis was similar in the two groups and there was no clinical evidence of any inhibitory effect of the penicillin in the treated animals. The number of animals with visceral involvement was similar in both groups. Evaluation of the microscopic appearance of the eyes and viscera indicated less total ocular tuberculosis, less total ocular caseation, and less total ocular and visceral tuberculosis in the treated group however the analysis indicated that these findings were not statistically significant.

It was concluded that the sample of penicillin G used had no therapeutic effect on ocular tuberculosis in nonimmune rabbits.

FRANK W. NEWELL, M.D.

Norm 1 Optic Nerve: Classification of the Optic Disc Based on Branching of the Central Retinal Artery. EVERETT H. WOOD. *Arch. Ophthalm. Chic.* 1943 30: 305.

The author presents a classification of optic nerve types based upon division of the optic nerve into quadrants, and observation of the distribution of the four main branches of the central retinal artery in the various quadrants.

In a study of 500 individual, the most common type presented a distribution of both inferior branches in the nasal inferior quadrant with distribution of the two superior branches in the two superior quadrants (35.2%). The second most common type had a symmetrical distribution with branches in each quadrant (31%). The third most common type had the distribution of all vessels on the nasal side of the disc (16.6%). There were none of the type with all branches on the temporal one-half of the disc. Most of the individuals observed (53.4%) had dissimilar optic discs.

FRANK W. NEWELL, M.D.

Observations on the Pulse and Retinal Arterial Pressure. W. KAROLINSKY. *Brit. J. Ophthalm.* 1943, 37: 473.

This article concerns the arterial movements in the central retina of the eye which are magnified four ten times and easily studied.

In the fundus oculi we observe, simultaneously with the pulse arterial movements depending on the impetus given by the local artery. These movements appear in two phases. The first phase due to cardiac systole, is rapid the second, due to diastole is slow. Any other movements, viz., arterial dilatation and contraction do not take place. The

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Actinomycosis. J. ROBERT JACOBSON and RALPH B. CLOWARD *J. Am. Med. Ass.*, 1948, 137, 769.

The authors present a report of the first verified case of actinomycosis of the central nervous system with recovery. Prior to the advent of chemotherapy (1937) a review of the entire medical literature revealed some 108 cases of actinomycosis of the central nervous system. The disease was routinely fatal. After the advent of the sulfonamides and antibiotics several recoveries of systemic actinomycosis were reported. Recent literature has stressed the specific value of these drugs in actinomycotic infections.

A detailed case report is presented and the importance of the bacteriological examination is stressed. The average case shows thick pus in the spinal fluid with high cell counts predominantly polymorphonuclear leucocytes; sugar is absent. The temperature range from 101 to 102 F. The patients do not appear as toxic as would be expected from the abnormal findings noted in the spinal fluid. There is usually paralysis of several cranial nerves. The white blood cell count ranges from 17,000 to 25,000. Secondary hemiparesis of several cranial nerves. The white blood cell count ranges from 17,000 to 25,000. Secondary hemiparesis of several cranial nerves. The white blood cell count ranges from 17,000 to 25,000. Secondary hemiparesis of several cranial nerves.

This particular patient received intensive treatment with sulfadiazine, penicillin and streptomycin.

HOWARD H. LAWDER, M.D.

Treatment of Thoracogenic Brain Abscess. J. B. PEDERBACKER and T. HOMER SELLERS. *Lancet*, London, 1948, 2, 90.

A review of 20 consecutive cases of thoracogenic brain abscess revealed that 7 patients recovered from the cerebral infection and 6 were still alive. These 13 cases were observed among 100 patients with brain abscess who were treated in the Nuffield Department of Surgery, Oxford during the past 9 years. Thoracogenic abscess is usually discrete and in the main mass is often single and discrete and in the main mass is often single and discrete and in the main mass is often single and discrete.

Thoracogenic abscesses like metastatic tumors, appear to develop at the junction of gray and white matter and in only one case was there a deep seated lesion and this was in the optic thalamus.

Bacteriological findings included 10 different types of organisms and 2 that were sterile.

These abscesses are not generally considered suitable for the type of treatment which aims at radical removal in the chronic, encapsulated stage but the use of penicillin and sulfonamides has been of great aid in their successful treatment.

A detailed report of 6 cases is given and the method of treatment is described. Elimination of the chest sepsis or at any rate its control by minor surgical

and palliative measures should always be attempted so that the risk of cerebral infection is minimised. Radical surgical measures directed at the thoracic infection and its elimination should be taken. If the patient is very ill, a burr hole is made over the abscess and aspiration is undertaken on occasion the critical period. Radical removal can usually be undertaken if the patient's condition permits. Arteriography has been employed as a localising agent, although in other cases ventriculography is necessary.

It is advised that if the abscess is aspirated or sucked out in the acute stage the resulting cavity should be treated with penicillin at the time, and the dura and bone flap dusted with the abscess and its susceptibility to antibiotics should be determined at the earliest possible time. Closure without drainage powder. The bacteriology of the abscess should be determined at the earliest possible time. Closure without drainage powder. The bacteriology of the abscess should be determined at the earliest possible time.

The advent of any cerebral symptoms in a patient suffering from pulmonary infection calls for immediate neurological investigation for the possibility of a developing brain abscess.

HOWARD A. BROWN, M.D.

Transorbital Lobotomy. CHARLES H. JONES and JAMES G. SHAWKELLY. *Northwest Med.*, 1948, 47, 421.

A brief résumé is given with regard to prefrontal lobotomy and its further development in this country and abroad.

Transorbital lobotomy was introduced by Fiamberti in 1937. The technique as developed by Free man in this country is described. It includes two electrically produced convulsions and lobotomy is performed on one side during the coma following the second seizure. This is immediately followed by a third electric shock, and the other side is operated upon during the ensuing coma. The instrument consists of a pointed, circular shaft of steel 14 cm. long with an attached handle. It is calibrated 7 cm. from the tip.

The patient is placed upon his back during the state of coma, and the eyelids are elevated by the operator who then pierces the orbital conjunctiva near the posterior margin of the conjunctival sac. The instrument is held against the nose and a small and parallel to the bridge of the nose and the anterior cranial fossa until the seventh centimeter mark approximates the margin of the upper eyelid. After its position is carefully checked, a lateral photograph is taken with the instrument in place. At this point the instrument is firmly fixed in the superior orbital plate and usually will not move if the operator's hand is taken away. However, the fixation is easily overcome as the lateral and medial movements are made.

3 It was evident to the author that definite end organ damage and profound functional loss could be produced by shock tubes that did no visible damage to the middle ear structures.

4 In the animals showing a partial functional loss of the tensor tympani response no uniform predilection for the high frequencies was noted.

5 Two functional reactions were observed (a) evidence of recovery within several hours after exposure (b) a rather rapid progressive obliteration of function within a few minutes after the immediate postblast threshold was taken.

6. No clear-cut relation was seen between the partial loss of function and the position of damage in the cochlea.

JOHN J. BALLENGER, M.D.

PHARYNX

Neuron Arcs of Clinical Significance in Laryngology
A. C. FURSTENBERG and ELIZABETH CROSS, A
Otol Rhinol 1948 57 395.

Specifically, the text treats of certain respiratory reflexes and the neuron pathways along which they travel. An attempt is made to describe various nerve circuits composed of peripheral nuclear and associated routes and to explain by reason of their position, relationships and function, some of the phenomena observed in clinical practice.

While much of this subject may be of only academic interest it is nevertheless axiomatic that the basic sciences form the foundation of medicine. From a knowledge of them one may travel in any direction. A veritable panorama of opportunity is exposed to the individual whose interest is grounded in the fundamental principles of some phase of science the opportunity for intelligent observation, research the development of therapeutic facts and the ability to put these facts into discriminate practical usage. It may not be too much to expect, therefore that this anatomical study of some of the reflexes of respiration may serve as a common core about which a better understanding of respiratory symptoms and a greater knowledge of rational methods of treatment may be developed.

Among the respiratory reflexes of clinical importance are hiccough, coughing, and sneezing. The author believes that the symptom of coughing is more often than not an expression of some strong feeling or impulse of a psychogenic nature.

The absence of pathologic changes about the brain stem in individuals who had died of meningitis gave rise to doubt that direct stimulation of the vagus nerves and later paralysis of them were responsible for the respective slowing and acceleration of respiration. The inquiry into a more rational explanation for these changes arose particularly from autopsy findings in cases of meningitis secondary to

nasal accessory sinus disease in which the emaciate was largely confined to the surfaces of the brain.

While the text probes only superficially into the emotional factors responsible for respiratory variations such as hiccough, sneezing, and coughing, it deals specifically with the central nervous apparatus along which emotional impulses are carried. A knowledge of these pathways and a better understanding of parent-child relationships may widen our knowledge of the psychology of cough and asthma.

In discussion of the reflex arc of sneezing an effort is made to offer an explanation on an organic basis for the occasional complaint of nasal obstruction after a submucous resection of the septum in a patient who has wide open nasal cavities.

Finally this initial inquiry into the nervous mechanism of respiration and its common variations leads one to the conviction that much more work needs to be done if we are to achieve a thorough survey of this subject. The one generalization that may be derived from this discussion is that the whole mechanism of respiration is a complicated one governed by a reflex arc and an equally important central nervous system component susceptible to emotional stimulation.

There are 4 drawings of the various nerve circuits described in the text.

JOHN F. DIXON, M.D.

Tonsillectomy Poliomylitis Survey—1947 D. VIN
S. CUNNINGHAM, *Laryngoscope* 1948, 58, 505.

In an attempt to elucidate the relationship between recent tonsillectomy and the contraction of poliomyelitis the author reports the statistical results of questionnaires which traced 43 per cent of the cases of poliomyelitis reported throughout the country in 1947. The report is contrasted with a similar one previously published, which gave analyses of 33 per cent of the cases reported in 1946.

The 1946 survey showed that in 2.5 per cent of all cases of poliomyelitis followed the disease was preceded by a tonsillectomy while in 1947 the figure was 0.5 per cent. In 1946 1.1 per cent of the cases of poliomyelitis were preceded by various operations other than tonsillectomy, whereas in 1947, 1.0 per cent of cases were preceded by other operations—about 4 times as many as were preceded by tonsillectomy.

In addition to the surveying of the cases of poliomyelitis, 5,439 tonsillectomies performed in 15 different states in 1947 were followed for a period of 3 months post-operatively. Among this total, 2 cases of poliomyelitis were discovered.

In conclusion the author states that he is more convinced than ever that there is no causal relationship between recent tonsillectomy and the development of poliomyelitis, and that when a bulbar poliomyelitis follows a tonsillectomy it is purely coincidental.

JOHN J. BALLENGER, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Carcinoma of the Premenopausal Breast. CHARLES M. WAGGONER. *Ann. Surg.* 1948, 137, 1356

The effect of ovarian function on the production of carcinoma of the breast has long been studied experimentally and in human beings. The palliation in breast malignancy after oophorectomy has also been shown. Widespread administration of estrogens however has been followed by relatively few coincidental. The author reports the case of a 44 year old woman with extensive carcinoma of both breasts and widespread metastases who six months previously (at which time the breasts were said to have been normal) was started on a course of theelin therapy for menstrual irregularities which at first had caused painful swelling of both breasts. The patient was considered to be in the terminal stage when seen but she began to improve and lived 19 months before succumbing to overwhelming metastases. At autopsy widespread disease was found including complete replacement of ovarian substance tumor. It is suggested that the patient's clinical improvement was due to the loss of ovarian substance occurring with peritoneal spread of the tumor.

Thirty nine additional cases of women under 50 years of age with breast malignancy are reviewed with regard to abnormal endocrine patterns as reflected in menstrual abnormalities. Thirty of these presented clinical evidence of hormonal imbalance. Specific factors remain unknown but the relation ship of ovarian hormones to breast malignancy is suggested by these cases. JESSE E. THOMPSON M.D.

TRACHEA, LUNGS, AND PLEURA

The Volume of the Bronchial Tree at Various Levels and Its Possible Physiologic Significance. A. C. HILTON and DAVID HILTON. *Ann. Otol. Rhinol.* 1948, 57, 324

There is a small progressive increase in the volume of the tracheobronchial tree from the larynx to the bronchi measuring 1.5 mm. in diameter. It is from 50 to 100 per cent. In this portion of the tree there does not seem to be any very effective air cleansing device except the direct impingement of the air on the mucous blanket lining the tree. There appears to be a very considerable expansion in the volume of the trachea in tubes of less than 1.5 mm. in diameter. Before the cilia cease the tree has divided into bronchioles which number somewhere between 15,000 and 70,000 each of which is lined with ciliated epithelium and a sticky mucous blanket. The total circumference of these tubes measures many meters. This "bronchiolar filter" is an effective final device to protect the alveoli from dust and fumes which may gain

access to the trachea. It is probable that the cilia move off the mucous blanket, as is the case elsewhere in the tract. If sufficient secretion is produced than bronchiolar filter could be even more effective than the nose in dust removal and humidification. It does not, of course, protect the trachea and the larger bronchi from improperly prepared air. SAMUEL KARY M.D.

A Contribution to the Study of the Pulmonary Hilum. The Hilum of the Right Upper Lobe (Contribucion al estudio de los pediculos pulmonares. Pediculo lobar superior derecho). A. RUIZ LIARD. *An. Fac. med. Montev.* 1947, 33, 1039

The present article coming from the Instituto de Anatomia Normal of the Facultad de Medicina de Montevideo represents a rather exhaustive treatise on the descriptive anatomy of the bronchial and vascular supply to the right upper lobe of the lung. A brief description of the grouping of hilar lymph nodes is likewise given.

In summary form and without any attempt to correlate the nomenclature used the principal points may be given as follows:

The bronchus to the upper lobe is distinguished by its short length (10 to 12 mm.) and its virtually horizontal course. It divides into three branches: (1) apical which further gives off an anterior posterior and apicoaxillary branch; (2) ventral which gives off a superior and inferior ventrosternal branch as well as a ventroaxillary branch and a dorso-vertebral branch.

The arterial supply can be classified into three sources of origin: (1) the constant supply reaches the lobe through the first branch arising from the pulmonary artery, and supplying 50 to 100 per cent of the blood to this lobe (the pattern of branching exhibited by this artery is highly variable); (2) in 92 per cent of cases there are branches to the lobe which arise directly from the level of the principal lobar artery below the level of the principal lobar artery referred to above; they occur as ventral or dorsal branches and supply the ventrosternal segments of the lobe; (3) quite rarely (in 2 to 4% of cases) there may be vessels supplying the upper lobe as referred to and (3) quite rarely (in 2 to 4% of cases) there may be vessels supplying the middle lobe or to the dorsal segment of the artery to the lower lobe.

The venous trunks from the upper lobe unite to form the vein of the middle lobe or to the superior pulmonary vein. From the upper lobe the principal branches are referred to as apicoventral, apicoaxillary and ventroaxillary, and (2) the superficial tributaries which are called either mediastinal or fissural.

Very little resistance is felt to the passage of the narrow shaft as it is moved through the brain. A movement of 15 degrees medially and laterally severs the connections in the subcortical white matter and displaces the cortical art. vessels without lacerating them. A greater sweep of the instrument is unnecessary and may be dangerous. On being brought back to the midline of the orbit, the instrument is carefully withdrawn. With the withdrawal of the instrument a gauze pad soaked in a saturated solution of boric acid is applied over the eye with firm pressure to minimize hemorrhage into the orbital tissues.

No preparation of the operative site is necessary as the instrument is introduced into a sterile field—the conjunctival sac.

Forty-one patients whose cases are reported in this series were subjected to this type of operative procedure. There were 26 cases of schizophrenia, 6 cases of manic depressive psychosis, 3 cases of agitated depression, 2 of severe mixed type psychoneurosis, 2 of obsessive compulsive neurosis, 1 case of ritualistic melancholia, and 1 case of intractable pain of the thalamic syndrome. Twenty-six of the patients were women and 15 were men. The oldest patient was 67 years of age and the youngest was 18 years.

The results were classified as "good," fair, and poor. A good result is one in which the patient has the capacity to adjust outside the hospital with little or no supervision. A fair result implies that the patient can get along on a parole status with moderate supervision or that there has been a striking improvement in his behavior to a point where only little hospital supervision is required. Although the patient may show improvement in many ways the result is regarded as poor if considerable hospital supervision is necessary.

Thirty-five patients whose postoperative period was longer than 1 month were graded on the above basis: 16 received a good result, 12 a fair result and 7 a poor result.

The immediate postoperative course is said to differ sharply from that of prefrontal lobotomy and the patient is ambulatory as soon as the effect of electroshock anesthesia subsides. He may present one or two black eyes as the only physical evidence of having undergone surgery. No deaths were reported.

A unilateral ptosis of the upper eyelid was produced in 4 cases but gradually disappeared.

PERIPHERAL NERVES

Lacerative Lesions of the Brachial Plexus (Le lésions du strapasso del plesso brachiale). LEONARDO GUERCHI, *Chir. org. modim.*, 1948, 31: 97.

Eight cases of paralysis of the brachial plexus from the Putti Institute of Bologna, Italy form the basis of this report. All of the patients were soldiers. In 5 cases the injuries were due to motorcycle traffic acci-

dents; in 1 case the injury occurred as the result of a falling beam during bombardment; in 1 as the result of a fall from a horse; and in 1 as the result of a railroad accident.

In all of the injured the plexus was exposed upward to the point of issuance of the nerve roots from the intervertebral foramina and downward into the axilla, if indicated, through an incision from the upper end of the sternocleidomastoid muscle across the clavicle and then downward and outward onto the chest. The clavicle was cut through and, if necessary for exposure or nerve suture, a section of this bone was resected together with the subclavicular muscle.

In 2 cases the symptomatology indicated the interruption of the fifth and sixth cervical roots; in 5 cases the syndrome was that of total interruption of the plexus; and in the remaining case the condition was diagnosed as a dissociative paralysis of the lateral and posterior fasciculi.

Of the 2 cases of upper root disturbance no interruption of the nerves was found at operation; in one, however, a simple nerve lysis was done and the motor function of the muscles returned to normal; some sensory disturbance remained. In the other patient there was a covered interruption of the fifth root and a laceration of the sixth spinal nerve root from the medulla. Here the peripheral stumps of these nerves

re united by nerve suture to the fifth root and the patient recovered active contractions in the bicipital, pectoral and long supinator muscles.

In the instance of dissociated paralysis also, the peripheral trunks (axillary and radial nerves) could be reunited to their corresponding posterior fasciculus and the interrupted part of the lateral fasciculus could be reunited *in situ*. This patient regained active contraction of the deltoid and triceps muscles. In one case in which suture was possible all three fasciculi were reunited to their proximal stumps; here, however, the operation has been too recent for evaluation.

In the remaining 4 cases, a careful and extensive nerve lysis was all that could be attempted; however, in 3 of these the pains were largely or completely relieved. In the fourth patient, it is believed that the source of the pain was an irritative condition in the spinal cord itself, resulting from the injury suffered in avulsion of the nerve roots, and that only a chordotomy would bring alleviation.

The author reports no experience in implanting the peripheral stump of the interrupted nerve into an intact root and he does not subscribe to the suggested periaxillary sympathectomy for the relief of pain in these cases, since he thinks that neurolysis will accomplish all that can be done. Early operation is favored, and excellent results are reported for the combining of intramuscular injections of cytra (8 to 10 c.c.) with general ether anesthesia, and for the use of an aspirator and the electrocoagulator during the operation in these highly vascular lesions.

Attended with Pleural Complications

Acta chir scand

The writer reports a material comprising 100 cases of pulmonary abscesses of which 32 were associated with pleural complications. The incidence of pleural complications is the same in the presence and absence of stenosing bronchial affections. They are most common in connection with abscesses of the lower lobes. Definite rupture of the abscess was demonstrated in 21 cases. Putrid effusion was found in 23 cases 17 of which exhibited nonhemolytic streptococci. In a large number of cases there will be complete incongruence between the pleural effusion and the abscess and those of the pleural effusion find in the sputum and definite perforation set in when the disease

The treatment has primarily been directed against the pleural complication which has quickly been subjected to treatment as a rule by rib resection (third) and suction drainage. In 8 cases operation was required.

Eight patients died in the department, 4 after discharge. One of the patients still has a small bronchial fistula but the others (10) are well. The follow up period ranges from 1 to 3 years. The prognosis is chronic serious in patients already affected with a chronic disease of the lungs. It was chiefly such patients who died. Otherwise pleural complications of pulmonary abscess.

abscesses usually run a benign course with adequate drainage

The Treatment of Bronchiectasis OSCAR J. CANAL
Rosario 1947 1s 33s
The author presents a general survey of the treatment of bronchiectasis. He points out the limitations of medical management and emphasizes the dismal outlook for untreated resection in extrapulmonary bronchiectasis. The justification for the bronchiectatic segments of lung is presented, as well as a consideration of the problems involved in bilateral bronchiectasis. A personal series of 100 cases is presented. The bulk of the discussion is devoted to the treatment of the disease. Brief reference is made to a personal collection from 1900 to 1940 on material collected from 1900 to 1940.

The Drawbacks Encountered in the Local Treatment of Pleural Empyema with Chemotherapy and Antibiotic Agents. JAMES L. HANSEN

Drawbacks Encountered in the Treatment of Pleural Empyema. JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 1948 66 509.

In the local treatment of empyema, early and frequent puncture aspiration of the pus and intrapleural injection of chemotherapeutic and antibiotic agents in large doses are of great value during the first stage of the disease. In nontuberculous cases this treatment should, however, be replaced by permanent drainage if freedom from symptoms, a clear thoracic field and a fully expanded lung on the x ray film are not obtained quickly. It depends to a great extent on the care and thoroughness with which the treatment is sufficient and which patients require treatment of a drain. There is hardly any puncture insertion of the puncture method alone. I doubt that a few specially trained men, particularly therapists are capable of this therapy. Moreover, empyema in the later stages of empyema requires this drainage. Therefore, more

In tuberculous empyemas the mixed infection type it is advisable to prolong the course of punctures and injections.

The present report covers the authors' experience with 30 cases of acute nontuberculous empyema in

The lymph nodes at the hilum are divided into groups (1) the superior group, located just below the azygos arch (2) the middle group located between the main pulmonary artery and its chief branch to the upper lobe and (3) the inferior group located in front of the hilar portion of the lobar vein. The chief group of lymph nodes is the middle group, the inferior group is present in only 20 per cent of cases.

The treatise is illustrated by 9 three-colored plates and is accompanied by schematic drawings that are well labelled.

Practical points of application to the surgical removal of the right upper lobe are made. Twenty seven bibliographical references are added.

HIRSH T. LANGSTON, M.D.

Hernia of the Lung (Hernia de pulmón) ALFONSO J. PAVLOVSKY and VICENTE LAVENIA. *Bol Acad Argent ci* 945, 32: 29.

Herniation of the lung is a rather rare condition even though references to it have been made by ancient writers.

Its occurrence implies a forceful increase in intra-pulmonary pressure (such as may occur during coughing, defecation, vomiting or sudden effort against a closed glottis) impinging on a defect in the chest wall. This locus minoris resistentiae may be the result of trauma and local muscular atrophy or of congenital malformation. It occurs most often in the anterolateral portion of the chest wall. The character of the swelling and its increased size during forced expiration should suggest the diagnosis of hernia. The roentgenogram can usually be depended upon to demonstrate the exact nature of the lesion when taken tangentially to the chest wall.

The authors believe that hernia of the lung should be treated surgically and that other forms of palliative management such as the use of trusses are unsatisfactory. Their method of repair consists essentially in mobilization of the sac and its careful closure. This portion of the procedure implies an open pneumothorax and endotracheal anesthesia is recommended. The chest wall defect is closed by suture, reinforced by suturing an osteoperiosteal flap obtained from the rib above the defect to a periosteal flap obtained from the rib below the defect and imbricating them over the hernial ring. The superficial tissues are carefully closed over this in anatomical fashion with overall pressure dressings.

A case of lung hernia is reported in a 38 year old laborer whose acute symptoms were brought on by heavy lifting. The hernia occurred at the site of a stab wound incurred 17 months previously. This method of repair was satisfactorily employed.

HIRSH T. LANGSTON, M.D.

Experiences in the Surgical Treatment of Pulmonary Stenosis. JOHN R. PAINE and RICHARD L. VARGO. *Surgery*, 945, 24: 355.

The authors review their series of 43 patients between the ages of 15 and 24 years, on whom they

performed the Blalock-Taussig operation for the relief of pulmonary stenosis.

The most common type of shunt made was an end-to-side anastomosis of the subclavian artery to the pulmonary artery (35 cases). In 5 cases an end-to-side anastomosis of the innominate artery to the pulmonary artery was done and in 3 cases an end-to-end anastomosis of a subclavian artery to a branch of the pulmonary artery was done. In 5 cases only exploration of the mediastinum was done. In the recovered patients almost uniformly good results presenting increased physical endurance were observed; there were also increased oxygen saturation of the blood at the average of 15 per cent and a correlated decrease in polycythemia and cyanosis.

Nearly all of the patients showed postoperative pleural fusion which in 8 instances necessitated aspiration because of dyspnea. Also there was noted an increase in the size of the heart after operation which was thought to be indicative of mild cardiac decompensation.

In 3 patients diffuse brain damage due presumably to inadequate oxygenation was noted. Two of these patients never regained consciousness. Three patients also died of cardiac standstill in spite of the injection of 1 per cent novocain into the vagus nerve and around the hilus of the lung.

The authors emphasize that these patients are best handled by a team consisting of a pediatrician, a roentgenologist, an anesthetist and two surgeons.

In view of the technical difficulties of an anastomosis on the right side the authors believe that in cases in which the preoperative oxygen saturation is over 50 per cent and only a small shunt is needed, an approach on the left side utilizing the subclavian with the pulmonary artery is preferred to the formation of an innominate-pulmonary artery shunt which has an appreciably higher mortality.

The authors elaborate on the technique and the anesthesia used, and also the psychometric observations before and after operation.

JAMES C. MACMILLAN, M.D.

Preoperative Bronchoscopy in Lobectomy for Tuberculosis (La broncoscopia preoperatoria nella lobectomia per tubercolosi) M. ARSLAN and A. SCARPA. *Minerva med* T 945, 39: 345.

The authors suggest preoperative bronchoscopy study of the tracheobronchial tree in tuberculous patients in whom lobectomy is contemplated, and present a report of 3 cases in which such a study was very helpful.

In the first case the bronchoscope study revealed a large rigid cavity which contraindicated surgery.

The second case was that of a patient 33 years old, in good physical condition, apyretic, and with a large cavity in the right superior lobe of the lung. Bronchoscopic examination revealed the bronchus to be fibrosclerotic and stenosed up to its bifurcation, which necessitated a reserved prognosis. The operation though technically difficult, was successful however on the twentieth postoperative day the

SURGERY OF THE THORAX

Usually the structure or structures which must be treated surgically are either the ductus arteriosus or some structure which lies in the same side of the body as the ductus therefore it is advantageous for the surgeon to know, preoperatively on which side the ductus arteriosus lies in order that he may perform the thoracotomy on that side. Since the roentgenologist is not able to visualize the ductus arteriosus directly he must rely on indirect evidence in predicting its situation. The following rule although not infallible will be helpful. The ductus arteriosus usually lies on the same side of the thorax as does the upper portion of the descending aorta. By visualizing this site of the latter structure the roentgenologist may predict with reasonable accuracy the situation as to the proper side on which to guide the surgeon as to the ductus arteriosus and to perform the thoracotomy.

ESOPHAGUS AND MEDIASTINUM

ESOPHAGUS AND MEDIASTINUM.
Combined Left Abdominal and Right Thoracic Approach to Resection of Esophageal Neoplasms. JOSEPH E. BLACKMUN. Surgery 1948

Progress in surgical therapy of neoplasms of the esophagus may be attributed to several factors: improved anesthesia, more adequate preparation and improved antibiotic therapy, more adequate blood replacement and increased knowledge of thoracic surgery. The author mentions a few disadvantages to the thoracoscopic and thoracolumbar approaches and subjects to a major procedure that the lesion be removed in order to avoid the

The author mentions a few disadvantages to left thoracotomy and therefore abdominal approach. The patient may be subjected to a major procedure in the thorax, also there is a tendency to compress the liver. Also there is a tendency to involve the amount of tissue resected on the proximal side of the neoplasm. Disturbed physiology results from pulmonary involvement of the right main bronchus. Involvement of the right main bronchus makes the procedure more hazardous from the left side. Crushing of the middle pleura and azygos vein makes the procedure difficult with identification of the vessels. The development of more hazardous results in this area favors the development of phrenic nerve results in difficulty with the development of collections of fluid in this area. The development of collections of fluid in this area favors the development of atelectasis and diminishes the power of the lung. The author made the procedure by performing the procedure on the right side. The author believes that the procedure is adequate as a procedure for the removal of the tumor.

electronic of the anastomosis and the technique of electrostimulation of the splanchnic nerves. In developing his technique, he believes that the procedure of cadaver dissections and later performance of the procedure on patients is adequate as a can- cer operation. He believes that the phrenic nerves minimize the incidence of the diaphragm facilitated at the lesion. He believes that the procedure is technically less traumatic than the procedure of the incision in the diaphragm proximal to the lesion. He believes that the procedure of the incision in the diaphragm proximal to the lesion is more difficult and consumed a great deal of time. He believes that the procedure of the incision in the diaphragm proximal to the lesion is more difficult and consumed a great deal of time. He believes that the procedure of the incision in the diaphragm proximal to the lesion is more difficult and consumed a great deal of time.

The operative procedure is opened to the first stage and explored. The gastrocolic ligament is divided and dissection is continued by division of the left gastrophilic artery and the vasa brevia. The left gastric artery is divided close to its origin.

THE THORAX.

The gastrohepatic mesentery is divided to the dia phragm. The peritoneal reflexion from diaphragm to esophagus is severed. The technique differs from that of Lewis in that the right crus of the diaphragm is not divided. At this point care must be taken not to injure the thoracic duct or the right inferior phrenic artery. The esophagus is freed from the mediastinum for about 3 inches and the abdomen is closed.

In the second stage of the operation the right chest is opened through the bed of the fifth, sixth, seventh or eighth rib. The level of the lesion is exposed for about 3 inches above and 3 inches below the lesion. Local incision is made from the level of the lesion

The patient was admitted to hospital because of his condition and remained there until he died 5 days later. When first observed the patient stated symptoms had begun to develop about 3 months previously. He exhibited a massive edema of the entire right and the right shoulder and right side of the thorax and upper chest were an arc and over the neck and face. About the rest were an evident sensory venous congestion and dilatation. There was a typical Homer's syndrome of the right eye and paralysis of the right recurrent nerve (paralysis of the right vocal cord). The physical findings on roentgenological examination demonstrated massive involvement, apparently filling the second and third ribs on the right side. Fever was irregular and the patient constantly complained of pains in the right arm and latterly of headaches.

Autopsy disclosed an atypical pavement epithelial carcinoma of the upper third of the esophagus.

Autopsy and
thelial carcinoma of the

patients treated with penicillin administered intrapleurally. There were 20 adults and 10 children in the series.

In 27 patients the pleural process was believed to have followed acute lung disease. Three cases represented traumatic hemothoraces that became secondarily infected. A pneumococcus was the infecting agent in 53.3 per cent of the cases, a streptococcus in 6.6 per cent, and a staphylococcus in another 6.6 per cent. In 9 cases the pleural fluid was sterile when first seen. In 6 of these 9 patients however penicillin had been administered previously. The average total dosage per patient was 450,000 units. The pleural fluid became sterile after from 1 to 3 instillations although as high as 26 thoracenteses were required in one instance to complete the treatment. Sterilization of the pleural fluid alone was not considered an indication to cease treatment, and caution against too early suspension of therapy is sounded.

Penicillin was given systemically in addition to the intrapleural dose to the majority of patients because of the lung pathology or the advent of some complication.

Only one case is admitted to have become chronic. The follow-up on the majority of the remaining patients had been of 2 to 3 months duration and they are reported as being well. The duration of the illness up to the time of discharge however ranged from 32 days to 170 days, 8 of these patients having spent 90 or more days in the hospital, and 17 of them 60 or more days.

The data furnished is essentially statistical. No documentation by roentgenography is offered.

HIRSH T. LANGSTON M.D.

HEART AND PERICARDIUM

Anomalies of the Derivatives of the Aortic Arch System. JESSE E. EDWARDS. *Med Clin. N. America*, 94:3, 9-5.

The primary purpose of this communication is to describe and to illustrate those anomalies of the derivatives of the aortic arch system which may interfere with the function of either the esophagus or the trachea. The subjects of persistent patent ductus arteriosus and coarctation of the aorta are not included. The majority of the anomalous configurations presented have been described. To these were added several configurations which, as far as the author knows, had not been reported heretofore. They stand out as distinct possibilities and consequently were included as hypothetical forms. This was done with the hope that when they are encountered they will be understood and not be viewed with undue surprise. Furthermore it is hoped that whoever observes these hypothetical possibilities will be stimulated to place them on record in order that the literature may contain a more comprehensive accumulation of this group of anomalies.

It is customary to employ the standard Rathke diagram of the six aortic arches in explaining the

developmental basis for the various anomalies of the aortic arches, and in relating the various types to each other. While this approach is perfectly logical and correct, the reader nevertheless, is likely to be somewhat confused. In the basic diagram of the six aortic arches, which is customarily employed the subclavian arteries lie caudad to the sixth arch. Yet, by the time of birth, important differences in the rates of growth of the portions of the aortic arch system result in the presence of the subclavian arteries in a cephalad position with respect to the sixth aortic arches.

The author believes that a better understanding of the relationship of the aortic arch anomalies, from a developmental point of view and with respect to each other can be had by an approach other than the employment of the basic primitive and diagrammatic six-arch pattern. To the author it seems best to employ as the basic pattern an anomaly which, while it contains the essential features of the primitive aortic arch pattern has also gone through the growth adjustments that take place in all persons.

The anomaly known as the functioning double aortic arch is chosen as the basic pattern. To fulfill completely the line of reasoning, this anomaly should contain right and left ductal arterial, but usually only one ductus arteriosus is present. The one adjustment that the reader must make is to realize that the functioning double aortic arch represents, with one exception, the primitive aortic arch pattern, in which growth adjustments have taken place. The exception is that one of the sixth aortic arches has largely disappeared.

In the author's opinion, malformations of the aortic derivatives may be divided into two groups, depending upon whether the ductus arteriosus takes its origin from the left pulmonary artery or from the right pulmonary artery. These groups are explained at length in the author's paper. Arbitrarily in cases in which the ductus arteriosus arises from the left pulmonary artery the anomalies are classified under group 1 while in cases in which the ductus arteriosus takes its origin from the right pulmonary artery the anomalies are placed in group 2. Group 1 is by far the larger of the two. Although exceptions to the rule occur the upper portion of the descending aorta lies on that side of the body on which the ductus arteriosus is found.

In those cases in which the upper portion of the descending aorta lies on the right side the lower portion of the descending aorta crosses to the left at about the level of the body of the eighth or ninth thoracic vertebra to leave the thorax through the aortic hiatus.

If a patient suffers from symptoms resulting from an anomaly of the derivatives of the aortic arch system, certain rules concerning surgical therapy can usually be followed. Relief may be obtained by division of the smaller of the two aortic arches, by division of that part of the arch which is atretic, by division of the ductus arteriosus, by dislocation of a common carotid artery or by division of a subclavian

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Peritoneal Reaction to Oxidized Cellulose. EUGENE T. DOWDY, *Arch Surg.*, 1948, 56: 386

Oxidized cellulose has recently been added to the armamentarium of the surgeon, a gauzelike material which is completely absorbed in the tissues and serous cavities. Its physical and chemical properties have already been described in the literature.

There has always been some concern expressed about leaving nonabsorbable materials in the tissues and especially in the serous cavities. Nonabsorbable sutures such as silk, cotton or nylon may be left in the tissues and serous cavities with a certain degree of impunity. Gauze sponges and packs have been left in the serous cavities with untoward results such as empyema, fistula formation and intestinal obstruction. They have also been left in the serous cavities for hemostasis and when they have been removed hemorrhage has often recurred or infection has been introduced.

The use of oxidized cellulose with thrombin as a hemostatic agent has been studied. A specific hemostatic action of its own which is due to the formation of a coagulum consisting of salts of cellulose acid and hemoglobin was observed. Oxidized cellulose has an untoward effect in bone. There is a delay in early callus formation in fractures which is due to the acidity of the gauze.

The primary reaction of traumatized peritoneum to oxidized cellulose is a fibroblastic proliferation to oxidized cellulose becomes flattened to produce a lining membrane.

Adhesions are formed between the omentum and intestine and the adjacent segments of intestine. The adhesions are permanent and are present after complete absorption of the oxidized cellulose.

The adhesions observed after immediate application of oxidized cellulose to the traumatized serosa are finer and less numerous.

The recurrence of adhesions cannot be prevented by oxidized cellulose. HARRY W. FINE, M.D.

Contribution to the Study of Pneumococcal Peritonitis (Contributo allo studio della peritonite pneumococcica) GIRO TARTARINI, *Arch Ital Chir.* 1947 69: 311

The problem of contributions to the literature based on study, experience, and research has not been solved. The differential diagnosis of acute pneumococcal peritonitis and the crisis of acute pneumococcal still creates a therapeutic dilemma. Whether surgical intervention as an emergency measure should be attempted in cases of pneumococcal peritonitis as in other types of septic peritonitis or whether it should be delayed or even advised against, is still a debated question.

After discussing the etiology, pathogenesis, pathological anatomy, symptomatology, diagnosis, prognosis and treatment of pneumococcal peritonitis the author painstakingly reports the clinical history of 7 cases of pneumococcal peritonitis which occurred among a series of patients operated on in the Civilian Hospital of La Spezia.

The condition occurred in children all girls, from 3 to 11 years of age. The disease is more common in children than in adults and is observed in girls more often than in boys. In 3 of the 7 cases the peritonitis was diffuse and in the remaining 4 the peritonitis was localized.

The first case was that of a girl of 9 years who was admitted to the hospital with a diagnosis of acute appendicitis. Physical examination revealed the presence of diffuse abdominal pain unaccompanied by muscular spasm. Examination of the lungs was negative. The patient suffered a severe persistent diarrhea which had been present since the onset of the disease. Vomiting was present, but not marked. Pneumococcal peritonitis was considered in differential diagnosis, but there was absence of labial herpes, vulvitis, and other extra-abdominal signs of the disease. Exploratory puncture was not made. Leucocytosis was present (20,500 white blood count with 92 per cent polymorphonuclear neutrophils). After a stormy period of remittent fever the patient developed signs of a localized abscess above the umbilicus. On the fifteenth day of the disease a midline incision above the umbilicus was made with the discovery of purulent peritonitis in the evacuated pus from which was identified the pneumococcus. Drainage was instituted and recovery was gradual. In the author's opinion a diagnosis of acute appendicitis was not justified in this case. The abdominal pain which was diffuse never became localized in the right lower quadrant. It was unaccompanied by muscular spasm on palpation. From the onset of the disease the patient suffered a persistent diarrhea a symptom which is rarely prominent in patients with appendicitis. Diarrhea occurs chiefly in those cases in which the appendix lies within the pelvis and it is not persistent or particularly severe. Vomiting was present, but not characteristic of that accompanying appendicitis.

When signs of a localized abscess did appear the localization was above the umbilicus.

The second case occurred in a girl of 4 years. The onset of the condition was accompanied by fever and persistent cough with scant expectoration. Bilateral bronchopneumonia was found in an x-ray examination of the chest. On the fourth day after the child's entry into the hospital a painful swelling unaccompanied by muscular spasm appeared in the abdomen. Diarrhea was present and vomiting occurred only once. Tuberculous peritonitis was considered as a diagnosis. Two days later a swelling appeared over

which had sprouted out into the right lung and spread into the right apical region of the chest, displacing downward and compressing the pulmonary tissues of the apex of the lung. The process had metastasized to the mediastinal and supraclavicular lymph nodes apparently on both sides of the neck and to the liver.

In the author's opinion this case of esophageal cancer verified at autopsy demonstrates that any sort of tumor of the upper mediastinum primitive or metastatic, is capable of producing a complete Pancoast-Tobias syndrome without reference to a primitive or metastatic malignant tumor within the parenchyma of the lung itself (upper lobe tumor of Pancoast). J. H. W. BERNHA, M.D.

Fibrosis of the Mediastinum with the Syndrome of Pancoast (Fibrosis del mediastino con síndrome di Pancoast). F. MARCOLONGO and P. C. FERABOLI. *Atti Accad. Med. Tor.* 948, 30-6.

The authors report the case of a 27 year old female who at 11 years of age had noted a weakening and atrophy of the left upper extremity which was especially evident in the hand. At about this time there appeared engorgement of the veins at the root of this arm and also at the base of the neck. This condition gradually became worse without, however, the development of any other symptoms worthy of note. A year previous to the time the patient was first observed a ptosis of the left upper eyelid developed and only a month previously there appeared a sudden burning pain extending downward along the left arm. At this time there appeared an irregular fever oscillating from 38° to 39° centigrade and the patient gradually lost 10 kgm. in weight. At examination the patient presented in addition some anemia and the roentgen examination disclosed a solid appearing sharply delimited tumor in the upper region of the left thorax which extended from the plane of the vertebral column which was pushed to the right, out to the left axilla. There was some enlargement of the left axillary lymph nodes and a dense homogeneous mass which was painful to pressure. A biopsy specimen from this mass disclosed histologically a simple fibroma. Pulsus differens and a difference in the blood pressure measurements on the two sides (left, 80/50 right, 115/65) were present.

Through an ample thoracotomy (third fourth and fifth ribs) the mass was successfully removed however after a period of 3 days the patient began to exhibit symptoms of collapse and she died on the

fifth day after the operation. At autopsy, degenerative signs were observed in the liver and kidneys and a brown atrophy of the myocardium was present. The tumor mass, which was 14 by 10 cm. in size proved again to be a fibroma without a mixture of other tissues. There were extensive necrotic areas involving the medial and anterior portions of the tumor.

The author designates the symptoms here present as a Pancoast syndrome although when that author described the condition in 1924 he intended it to apply only to malignant tumors of the pulmonary apex. It is believed that this is the first of these tumors to be diagnosed preoperatively.

MISCELLANEOUS

A Study of Intrathoracic Cysts Arising from the Diaphragm. P. E. A. NYLANDER and S. J. VIKARI. *J. a. chir. gyn. fenn.*, 948, 37-99.

Three cases of cysts in close relation with the diaphragm and located near the pericardium are reported. These cysts varied in size from that of a goose egg to one which was 23 by 13 cm. in size. Histologically the cysts were similar in that there was a firm inner layer and a dense outer layer, the outer layer being more vascular. One cyst was lined by endothelial epithelium. All cysts were removed surgically.

In discussing the origin of these cysts the authors point out that in their 3 cases the location was in the ventral median part of the right half of the diaphragm. They believe that Broman's investigations throw some light on the origin of these cysts. According to Broman the bursa infracardiac is a remnant of the right pneumatoenteric recess developed from the original pleuroperitoneal celomic cavity. The cranial part of the original recess becomes isolated and remains, as a bursa infracardiac, between the esophagus, the right lung, and the right half of the diaphragm. There are a bursa at first on both sides of the esophagus but the left one usually becomes atrophied. In some mammals this structure is larger than in man and the size varies greatly. Therefore it would seem natural for a bursa to persist as a cyst. In diagnosis roentgenology is the most helpful method. In one case the author used a diagnostic pneumothorax. Bronchoscopy and bronchography are not particularly useful in diagnosis of these cysts. Treatment of these cases is operative.

serum therapy, sulfonamides, and penicillin with the hope of ameliorating symptoms and modifying the prognosis of the individual case.

BLACKWELL MARSHALL, M.D.

Stainless Steel Wire for Abdominal Incisions and Hernias. A. LAWRENCE AXEL AND ALAN H. HUYER
Bull. N. Y. Acad. Med., 1948, 2: 379

Stainless steel wire was introduced for the closure of abdominal incisions by Babcock in 1934. The authors consider that the elimination of postoperative disruption is one of the most compelling factors in choosing stainless steel wire rather than catgut silk or thread in the closure of abdominal incisions. Abdominal disruption is due to one or more of the following causes: (1) interference with healing, or the dissolution of recently healed tissues by a local infection or by digestive enzymes; and (2) a disruptive force such as vomiting, coughing, abdominal distention, hiccupping, or sneezing.

The strength of a wound correctly closed with stainless steel wire is unaffected by time and is sufficient to withstand more than normal strains. It should therefore be used when there is any evidence of dietary deficiency or when there is any factor present such as malignant disease or jaundice. Wound infection accelerates the dissolution of catgut and also prevents normal healing. The same effects are presented by wounds bathed with biliary pancreatic, or other digestive ferments. If nonabsorbable ligatures such as thread and silk are used infection penetrates into the interstices between the filaments and cannot be thrown off by the body until the ligatures have themselves been discharged. Stainless steel wire is a single inert filament offering no concealment or retreat for micro-organisms. No matter how serious an infection is present, closing in over it without any risk of introducing heat sterilized, and there is no risk of introducing infection. The strength of stainless steel wire is such that no disruptive force can burst a wound which is closed in one of the manners suggested. Confidence in abdominal disruption is easily transmitted to the patient, who is thus more likely to co-operate willingly in getting out of bed within or about 24 hours after the abdominal operation.

The authors' experience dates from 1938 when wire sutures were adopted for the closure of all abdominal wounds, especially in the presence of potential infection and in cases of malignant disease. This practice was later extended to the repair of large incisional hernias and to other types of hernias requiring reinforcement of the defect. Thus far stainless steel wire sutures have been used in more than 500 major abdominal incisions in seriously debilitated individuals without a single instance of abdominal disruption or postoperative herniation.

In the past 4 years more than 300 hernial repairs have been made with stainless steel wire sutures.

Fig. 1. To illustrate the closure of paramedian incisions, the wire being retained.

Stainless steel alloy wire is not resorbable in the body fluids. The tissues react to its presence by formation of fibrous tissue but no inflammatory or foreign body response occurs. The wire acts as a framework over which the body deposits a dense mat of fibrous tissue over a narrow zone. The scar does not stretch. The wire suture does not act as an impediment to the healing of wounds infected at the time of operation or later.

In using wire sutures a principle must be adhered to. The anatomical relations of the parts sutured must not be distorted. Distortion implies tension and tension leads to tissue necrosis. Stainless steel sutures must therefore be laid in the tissues without tension. The dissection prior to suturing or during need involve only the immediate vicinity of the defect concerned. Fascial planes are thus not disturbed beyond a limited definition of the tissues and secondly the wire must never be used in all its break at a kink. Care must therefore be used in the processes of handling the wire.

The first complete stitch is passed through the tissues and the wire tied in a close reef knot so that the suture is taut but not tight. The short end is then gripped against the knot with a pair of artery forceps, cut level with the blade of the forceps and the stump twisted 180 degrees into the adjacent tissue. In thin subjects with little subcutaneous tissue it is advisable to cut the loose end of the wire flush with the knot.

In abdominal incisions of patients of normal build the peritoneum together with the posterior

the right trochanter. On exploratory puncture of the abscess the pus obtained revealed gram-positive diphtheroids. Operation on the fifteenth day of the disease through a midline incision below the umbilicus revealed a pneumococcal peritonitis, the causative agent being proved by bacteriological examination of exudate from the abdominal cavity. Drainage was instituted the trochanteric abscess was also drained. Recovery was gradual.

The third case of pneumococcal peritonitis occurred in a girl of 3 years, who was first admitted to the pediatric service for the treatment for worms. After some improvement following treatment, she developed a diarrhea remittent fever, and diffuse abdominal pain. She was then transferred to the surgical service. Examination of the chest was negative the throat was inflamed. The following day the fever subsided the diarrhea was checked and meteorism with a soft abdomen appeared. Pneumococcal peritonitis was suspected and a positive blood culture was obtained. A localized abscess developed in the region of the umbilicus. On the sixteenth day operation was performed with drainage of the abscess. Recovery was gradual. This was a classical case of pneumococcal peritonitis with typical onset intestinal signs with peritoneal invasion diarrhea, diffuse abdominal pain, remittent fever soft abdomen subsiding pain followed by meteorism, a positive blood culture, and signs of the development of a localized abscess in the second week. Operation on the seventeenth day revealed a circumscribed abscess below the umbilicus. Pneumococci were present in the purulent exudate from the abdomen. Recovery was gradual.

The fourth case occurred in a girl of 7 years, who was admitted to the hospital with a fever thready pulse intense dyspnea, extreme abdominal pain parched tongue sunken eyes, but with no herpes or vulvitis. Examination of the chest and respiratory tract was negative. The abdomen was distended and diffuse abdominal pain was present on palpation. After hospitalization for 3 or 4 days, some improvement was noticed then signs of a diffuse peritonitis appeared. Operation was performed with findings of a diffuse peritonitis which was due to the pneumococcus. Drainage was instituted. The patient died a few hours after intervention.

The fifth case was that of a girl of 8 years who entered the hospital for the relief of severe pain in the lower quadrant and fever. Prior to entry she had been troubled with meteorism and constipation. She had been purged. Physical examination revealed a patient with flushed face, a negative thorax, diffuse abdominal pain, more marked in the right lower quadrant and accompanied by slight muscular spasm in this region. There was present a vulvitis but there were no organisms demonstrable in the vaginal secretions. Blood examination revealed a leucocytosis of 23,500, but the blood culture was negative. On the eighth day of the disease operation was performed through a right rectus incision. A small amount of purulent exudate exuded from the

wound. The appendix was inflamed. An appendectomy was done and drainage instituted. The exudate showed pneumococci. Recovery was gradual.

The sixth case was that of a girl of 11 years, who entered the hospital for the relief of abdominal pain nausea and fever. After her entry these symptoms began to subside and a diarrhea developed. A few days later an umbilical fistula developed spontaneously through which exudate from a supposedly localized abscess flowed. Operation through a midline incision below the umbilicus was performed and drainage of a diffuse peritonitis was done. The causative agent was proved to be the pneumococcus. Recovery was gradual, with the development of an umbilical hernia which was later repaired.

The seventh case was that of a girl of 10 years, who was admitted to the pediatric service with a diagnosis of gastroenteritis. She had a past history of chronic indigestion. Five days before entry she had developed violent abdominal pain, vomiting, and diarrhea. These symptoms abated and a localized abscess beneath the umbilicus developed. A blood culture was positive for pneumococcus. Drainage of the peritonitis was carried out on the nineteenth day and recovery was gradual.

The author concludes from these cases that herpes labialis is not a constant sign of this disease and that it is difficult to demonstrate the presence of the pneumococcus in the blood and vaginal secretions. He considers the presence of vulvitis to be a very good presumptive sign and that the most important diagnostic element is diarrhea which is persistent, tenacious and initial. In all cases there is a severe onset with remittent fever, and acute diffuse abdominal pain unaccompanied by muscular spasm.

The possibility of an early diagnosis of pneumococcal peritonitis depends upon the recognition in female children of the presumptive signs of herpes labialis, vulvitis catarrhal inflammation of the respiratory tract, abrupt initial high fever with rapid remission diarrhea vomiting and diffuse abdominal pain unaccompanied by muscular spasm. To differentiate the condition from the onset of acute appendicitis is difficult. On account of this last fact, later mention is indicated immediately by many writers. The author recommends temporary supportive measures during the first 24 to 48 hours, until either the abdominal pain localizes or the acute initial symptoms begin to subside. In cases of circumscribed peritonitis he advises prompt drainage of the abscess in diffuse peritonitis he advises waiting until localization of the abscess occurs.

The author advocates general anesthesia except in cases in which the general condition of the patient is very grave. Under these conditions, local anesthesia is advocated. In all cases he advocates simple drainage without appendectomy. A midline incision above or below the umbilicus is employed depending upon the accessibility of the most dependent point of drainage of the abscess.

In the author's experience biological treatment has not met with success. In grave cases he employs

Fig. 2 Illustrate the closure of paramedian incisions when the wire is to be removed.

rectus sheath above the semilunar fold of Douglas is closed with a continuous catgut stitch in the usual manner. The muscle and the anterior sheath are then closed with a running figure-of-eight stitch (Fig. 1). In thin patients it is better to use interrupted sutures and to cut each wire flush with the knot or to use an alternative method as illustrated in Figure 2.

The technique of closure of hernial defects is described.

With little experience wire sutures can be handled with ease. Speed comes with practice. In respect to tensile strength, holding power, absence of inflammatory and foreign-body reaction, rapidity of healing, and to reduction of complications in an infected wound, stainless steel is better than catgut, linen or cotton thread or silk. Tantalum wire induces the same favorable response on the part of the tissues. It is easier to use and has less tendency to kink than stainless steel. It is, however, not as strong and is more brittle in the knot.

In about 1 case in every 200 a broken end of wire causes discomfort to the patient and needs to be removed under local anesthesia. This trouble has occurred in midline and paramedian abdominal closures in thin patients. In no case has the wire or a fragment of it, burrowed into the tissues more deeply and caused trouble.

The reopening of an abdominal incision closed with wire takes a little longer than that of one in which catgut or thread has been used but the method is easy. The skin and subcutaneous tissues are incised down to the wire loops. These are then defined sufficiently to be pulled up and divided between artery forceps, and the separate segments are then pulled

out, care being taken to remove the whole wire. The knife blade used for this part of the incision is rendered useless for further work. There is no difficulty in closing a wound with wire for a second time.

ROBERT TUNELL, M.D.

The Surgical Treatment of Strangulated Obturator Hernia (A proposito del trattamento chirurgico dell'ernia otturatoria strangolata) VITTORIO PATTINARI. *Ann. Ital. chir.* 1943, 25: 1.

The author describes the surgical treatment of obturator hernia using the external approach. An ample incision is made along the adductor muscles parallel to the gracilis muscle and the thigh is kept in flexion on the pelvis in abduction and external rotation with the heel resting on the opposite knee. The pectineus muscle is then cut near the pubic insertion and retracted distally. To attempt to go through the muscle would interfere with proper exposure, especially in the case of a strangulated hernia. The superior border of the obturator foramen must be properly exposed and in order to accomplish this, Gubernat's ligament and the crural arch are exposed. The latter is sectioned at the junction of the middle and medial thirds and the obturator foramen is thus exposed. The hernial sac is then opened, and the hernia is reduced. In the event that it is necessary to resect the bowel or exposure is not sufficient, one may extend the incision at the crural arch and then enter the peritoneal cavity and treat the hernial content in the best possible manner.

Repair of the hernia is made by the sectioned crural ligament which is transposed to cover the obturator foramen. The ligament is cut in such a way as to form a triangular limb which is then turned down completely to cover the obturator foramen, and fixed with several sutures. Above this is sutured the pectineus muscle. In all these maneuvers, the obturator nerve is carefully guarded.

The author states that use of the sectioned crural arch is also made in the repair of inguinal hernia with good results. As to the possibility of its causing a weakening of the anterior abdominal wall, the author believes this to be more theoretical than real. Moreover the procedure is usually followed in the cases of older women in whom the danger of inguinal hernia is minimal since they do not, as a rule, perform heavy work.

The objections to the external approach of those who favor the abdominal or internal approach, are discussed.

*These four groups of animals received 5 mgms. of histamine-in-beeswax intramuscularly per kilogram of body weight daily. Group 2 control experiments, Group 3 total extirpation of pancreas, Group 4 ligation of both pancreatic ducts, and Group 4, rendered diabetic by administration of alloxan.

†Summary of all lesions is given graphically in Fig.

‡This animal received only 100 mgms. of histamine-in-beeswax daily

total pancreatectomy comprised group 2 dogs in which the pancreatic ducts had been ligated comprised group 3 and dogs made diabetic by the administration of alloxan comprised group 4. All of the animals received similar intramuscular injections of histamine in beeswax by the technique of Hay Varco Code and Wangenstein.

A large series of dogs which had been pancreatectomized and maintained for a long period on a dietary regimen identical to this group also at the Surgical Research Laboratory of the University of Texas served as controls to demonstrate that ulcers do not develop spontaneously in these animals. Ligation of the pancreatic ducts was performed in 3 other dogs which were used as additional controls for group 3 and their sacrifice 2 months later showed that no ulcers had developed spontaneously. The milk and meat diet appeared to be adequate to protect against ulcer formation. Atrophy of all the pancreas except a thin cord of islet tissue indicated that complete blockage of the ducts was obtained.

The pancreas of the dogs in group 2 was totally extirpated by careful blunt dissection and the main duct ligated. Postoperatively careful management and replacement therapy maintained these animals in good condition indefinitely. Milk and corn syrup after 12 hours and ground raw horse meat mixed

with lecithin and pancreatin after 3 days constituted the diet. Two weeks postoperatively insulin was given and fasting blood sugar levels from 217 to 370 mgm. per cent indicated the completeness of the pancreatic extirpation. Histamine injections were not started until 2 weeks after operation.

The animals in group 3 had both pancreatic ducts isolated and cut between cotton ligatures. The pancreas was completely separated from the duodenum and a bit of omentum interposed. Postoperative care and feedings were the same as for the pancreatectomized animals except that the administration of insulin was not necessary.

For the purpose of studying the effect of eliminating the action of insulin the dogs in group 4 were made diabetic by the administration of 75 mgm. of alloxan per kilogram of body weight. The degenerative changes on beta cells by the action of alloxan are not readily accomplished in dogs so it was necessary to withhold food for 72 hours to render the 4 animals diabetic. After stabilizing these animals on daily insulin therapy to maintain reasonable blood sugar levels on the standard milk and meat diet daily injection of histamine-in wax was started.

A dosage of 5 mgm. of histamine-in beeswax per kilogram of body weight was administered daily. The animals were sacrificed when they showed signs

The Lytic Action of Saliva on Gastric Mucin from Patients with Ulcer. In Relation to the Pathogenesis of Gastric Ulcer (Il potere litico della saliva degli ulcerosi sulla mucina gastrica in rapporto alla patogenesi dell'ulcera gastrica) **POTERIO MIA**
Rev. Riforma med. 1913, 611-97

The author discusses the relation of gastric mucin to ulcer formation. It has a triple action: mechanical, chemical, and biological. Following his experiments on the action of saliva upon gastric mucin he arrives at the following conclusions:

1. Gastric mucin in normal individuals, as well as in those with peptic ulcer, loses its viscosity in time perhaps through the mucinase action of enzymes contained in the mucin itself.

2. The saliva of normal individuals has a minimal lytic, hence negligible action upon their own gastric mucin as well as upon the gastric mucin from patients with ulcer.

3. The saliva from patients with peptic ulcer possesses intensive lytic action upon normal gastric mucin as well as upon gastric mucin from patients with peptic ulcer, diminishing its viscosity.

4. The mucinolytic property is specific for saliva from patients with peptic ulcer.

In view of this data the author believes that the protective action of gastric mucin is deficient in ulcer patients and this loss is due to the diminished viscosity of the mucin rather than upon a diminished quantity. This view is further substantiated by the fact that there is a difference of opinion as to the amount of mucin found in patients with peptic

ulcer. Reference is made to different authors, some of whom maintain that gastric mucin is decreased while others maintain that gastric mucin is increased in patients with peptic ulcer.

LUIGI J. FROMMELT, M.D.

The Relation of Pancreatic Secretion to Peptic Ulcer Formation. Effect of Pancreaticotomy, Ligation of Pancreatic Ducts, and Diabetes on the Production of Histamine-Induced Ulcers in the Dog. **EGGAR J. POTTS, LOUIS J. BLANKOFF JR., and A. WILLIAM DELLOACH.** *Surgery* 1915, 24, 62.

The relationship between pancreatic secretion and peptic ulcer formation has been observed for some time. This relationship is now more important because of the advent of vagotomy and its possible modification of the effective parasympathetic innervation of the pancreas and the subsequent influence upon secretory activity. Duodenal ulcers may be produced by the deviation of the alkaline secretion of the pancreas through external fistulas, or the internal duodenoduodenal fistula, and by ligation of the pancreatic ducts. The occurrence of these ulcers has usually been considered the result of depriving the duodenum of the neutralizing influence of the bile and pancreatic secretions on the acid effluent from the stomach. When the duodenum is deprived of alkaline secretion by pancreaticoduodenal ulceration rarely supervenes. The difference may be that whenever the pancreas is present and the external secretions are excluded from the bowel in immediate contact with the gastric secretions, ulcers develop, while with simultaneous removal of the internal secretions by pancreaticoduodenal ulcers do not develop when the external secretions are excluded, because the blood sugar remains at a relatively high level without the stimulating effect of hypoglycemia on the acid secretion by the glands of the stomach.

Investigators have reported the incidence of experimental peptic ulcer following external pancreatic fistulas as being almost 100 per cent, following ligation of the ducts 29 per cent, and following pancreaticotomy 13 per cent. It may appear that ulcer formation in these situations is not explained adequately by failure of neutralization in the duodenum of the acid effluent of the stomach by the diverted alkaline secretions, and the question is advanced whether the pancreas has an intrinsic influence upon ulcer formation other than that of mere alteration of the duodenal contents.

Statistical studies indicate that peptic ulcers develop infrequently in diabetic patients. From 50 per cent to 40 per cent of diabetic patients exhibit acidity, which may be a related factor.

Both the internal and external secretions of the pancreas may be implicated in ulcer formation. This study concerns certain aspects of the influence of the secretory activity of the pancreas upon the formation of ulcers induced by continuous histamine stimulation of the dog.

Sixteen dogs were divided into groups of four. The controls were placed in group 1, dogs having

Fig. 1 (Potts et al.) Schematic demonstrations of the extent and distribution of ulcerations caused by histamine-in-beeswax with the alterations of pancreatic status.

anastomosis In this group 3 deaths occurred in the immediate postoperative period, 2 from shock and 1 death from pneumonia. Four patients died of metastases, in 3 months, 18 months, 19 months, and 20 months, respectively following resection. One patient with extensive ileocolic and rectal sarcomatosis was carried along favorably with deep x-ray therapy and was living and well 18 months after resection. Only 2 patients are living and entirely free of recurrence 18 months and 3 years respectively after resection. Both of these patients had resections for leiomyosarcoma. The 3 patients who were not operated upon died shortly after admission. Resection was performed in all 6 cases of benign tumors—side-to-side anastomosis being done in 5 cases and end-to-end anastomosis in 1 case. Three of the patients died—2 following operation and 1 in 6 months from an antecedent carcinoma of the cervix. The 3 remaining patients recovered and are well.

All patients with carcinoma succumbed because of the intrinsic malignant disease which established the fact that with the present treatment of malignancies of the small bowel the over-all prognosis is extremely discouraging.

An exhaustive review of the literature concerning tumors of the small bowel is presented and the 19 cases in this series are discussed in detail.

ELEMENT D. BLOOMENTHAL, M.D.

Ileus in the Course of Acute Appendicitis (Ileus im Verlauf der akuten Appendicitis) GEORG SCHÖTZE. *Chirurg* 1948 19 105

Ileus may be the cause as well as a sequel of acute appendicitis. As an example of the first possibility the author refers to a case in which partial obstruction by a carcinoma of the ascending colon led to an acute appendicitis caused by the accumulation of feces. On the other hand symptoms of a paralytic ileus can be produced in the very beginning of a severe attack of appendicitis without the presence of generalized peritonitis.

While these are comparatively rare occurrences ileus is a frequent postoperative complication. It is of greatest importance for a correct prognosis and treatment to differentiate between paralytic and mechanical ileus although mixed forms of both types occur and may complicate the evaluation.

In most cases paralytic ileus is a sign of generalized peritonitis. However laparotomy often reveals that only a small part of the peritoneum is involved in spite of a complete paralytic ileus. In such cases early surgery may save the patient.

Mechanical ileus may be caused by adhesions, kinking or strangulation of a loop of the small intestine or by volvulus or intussusception. These complications occur as a rule in a late stage of appendicitis with or without operation.

of having developed an ulcer such as anorexia, vomiting, bloody stools, and ill appearance (Table I).

The control dogs in group 1 were divided into two groups. 3 dogs received a dog biscuit diet and 3 received the standardized diet (meat and milk) fed to all animals included in this study. The 3 animals on the routine dog biscuit diet developed typical single ulcers in the first part of the duodenum. The 3 dogs on the standardized meat and milk diet showed no signs of ulcer development; they were sacrificed on the forty-fifth day and one had a single small duodenal ulcer and the other none. Apparently the meat and milk diet prevented ulceration in one dog and ameliorated it in the other.

In the depancreatized dogs (group 2), severe multiple ulceration of the duodenum developed within 4 to 7 days of histamine administration. Two of these animals died; 3 had perforations and bleeding occurred in all 4 dogs.

Three of the 4 dogs with ligated pancreatic ducts, in group 3, died within 6 days. Three had perforations and all showed gross bleeding.

None of the animals with alloxan diabetes, in group 4, showed signs of ulcer formation. A single duodenal ulcer was present in one of the dogs.

These studies did not demonstrate that diabetes alters the tendency toward histamine-induced ulcer formation. No inhibitory effect on the formation of peptic ulcers was produced by the diabetic state. A point of practical significance derived from the experiments is that removal of the pancreas or ligation of its ducts as is frequently performed in surgical procedure is not without some danger of postoperative ulceration. It would seem advisable to reanastomose the pancreatic duct to the duodenum or jejunum whenever possible following resection of the head of the pancreas.

ERNEST D. BLOOMENTHAL, M.D.

Tumors of the Small Intestine. HOWARD A. WEINBERGER and RUDOLF M. PALTAY. *Surgery* 94:8 14-15

Tumors of the small bowel are rare in comparison to tumors which are situated at the extremities of the gastrointestinal tract. It is important to diagnose and treat tumors of the small bowel because they are extremely lethal.

In a span of 40 years, 20 primary tumors of the small bowel were discovered at the Lenox Hill Hospital in New York City. Ampullary tumors of the duodenum were omitted because they are probably of duct origin. During this period, 14 neoplasms of the gastrointestinal tract were observed thus establishing a rate of 1 small bowel tumor to every 71 neoplasms elsewhere in the gastrointestinal tract.

Only 10 cases were available for study as the clinical record of one case was missing. Thirteen of the lesions were malignant and 6 were benign. The distribution between men and women was about equal. The average age of patients with benign tumors was 45 years and of patients with malignant tumors, 5 years.

Among the patients with malignant tumors, there was no instance of acute fulminating onset without preceding symptoms and the average duration of symptoms here was 10 months (from 1½ to 48 months). In the group with benign tumors, the duration of symptoms varied from an acute fulminating onset, due to sudden intestinal obstruction, to a period of 36 months.

In patients with malignant tumors, usually the chief symptom was pain. This occurred in 9, or 70 per cent, of the 13 patients and was usually described as abdominal discomfort of an intermittent aching character. Six patients manifested bleeding and 4 complained of diarrhea, constipation or alternation of the two. Weight loss, anorexia and cachexia were present in 11 of the 13 patients. Seven exhibited obstructions, and in 5 there was a palpable mass.

Of the 6 patients with benign tumors 4 complained of pain. Diarrhea and constipation were noted in 3 patients and bleeding occurred in 1 patient. Obstruction occurred in 3 cases and a mass was palpable in 3.

The symptoms varied from minor gastrointestinal distress to acute fulminating obstruction. Patients with persistent unexplained gastrointestinal complaints should be subjected to a careful roentgen examination of the small bowel pattern, as well as a roentgenological study of the remainder of the gastrointestinal tract. It may be necessary to resort to exploratory laparotomy.

In 6 instances of malignant and in 3 instances of benign tumors, x-ray studies were not made, usually because obstruction was present, or the patient was in extremis on admission. In the remaining 7 patients with malignant tumors, obstruction was demonstrable in 4 by roentgen examination. In one of these obstruction was interpreted as due to neoplasm. Two of the 7 cases studied by x-ray examination exhibited what were interpreted as filling defects due to tumor.

In the 3 cases of benign tumors which were subjected to x-ray study 1 tumor was registered as a negative examination, 1 as a mechanical obstruction of the ileum, and 1 as a filling defect. X-ray studies of the small bowel are generally not as satisfactory as those of the stomach or colon. Careful serial fluoroscopy and flash films of the small bowel following barium ingestion are essential.

The types of tumors encountered with their location, and the intussusceptions are listed in Table I.

It was interesting that 3 tumors of the duodenum were malignant and intussuscepted. Six tumors of the jejunum were malignant and 1 was benign and of these 3 were intussuscepted. Four tumors of the ileum were malignant and 6 were benign, and half of each of these were intussuscepted. The fact that lymph node metastases were largely concentrated in the large nodes at the root of the mesentery near the large mesenteric vessels made resection doubtful or impossible.

Ten of the 13 patients with malignant tumors were operated upon. 8 undergoing primary resection with

TABLE I. DEMONSTRATING DISTRIBUTION PATHOLOGIC TYPES, AND FREQUENCY OF INTUSSUSCEPTION IN THIS SERIES OF SMALL BOWEL TUMORS

anastomosis. In this group 3 deaths occurred in the immediate postoperative period: 2 from shock and 1 death from pneumonia. Four patients died of metastases in 3 months, 18 months, 19 months, and 20 months, respectively, following resection. One patient with extensive ileocolic and rectal sarcomatosis was carried along favorably with deep x ray therapy and was living and well 18 months after resection. Only 2 patients are living and entirely free of recurrence 18 months and 3 years respectively after resection. Both of these patients had resections for leiomyosarcoma. The 3 patients who were not operated upon died shortly after admission. Resection was performed in all 6 cases of benign tumors—side-to-side anastomosis being done in 5 cases and end-to-end anastomosis in 1 case. Three of the patients died—2 following operation and 1 in 6 months from an antecedent carcinoma of the cervix. The 3 remaining patients recovered and are well.

All patients with carcinoma succumbed because of the intrinsic malignant disease which established the fact that with the present treatment of malignancies of the small bowel, the over-all prognosis is extremely discouraging.

An exhaustive review of the literature concerning tumors of the small bowel is presented and the 19 cases in this series are discussed in detail.

ERNEST D. BLOOMENTHAL, M.D.

Ileus in the Course of Acute Appendicitis (Ileus im Verlauf der akuten Appendicitis) GEORGE SCHÖNBERG, *Chirurg* 1948 19: 103

Ileus may be the cause as well as a sequel of acute appendicitis. As an example of the first possibility the author refers to a case in which partial obstruction by a carcinoma of the ascending colon led to an acute appendicitis caused by the accumulation of feces. On the other hand symptoms of a paralytic ileus can be produced in the very beginning of a severe attack of appendicitis without the presence of generalized peritonitis.

While these are comparatively rare occurrences ileus is a frequent postoperative complication. It is of greatest importance for a correct prognosis and treatment to differentiate between paralytic and mechanical ileus although mixed forms of both types occur and may complicate the evaluation.

In most cases paralytic ileus is a sign of generalized peritonitis. However, laparotomy often reveals that only a small part of the peritoneum is involved in spite of a complete paralytic ileus. In such cases early surgery may save the patient.

Mechanical ileus may be caused by adhesions kinking or strangulation of a loop of the small intestine or by volvulus or intussusception. These complications occur as a rule in a late stage of appendicitis with or without operation.

As to the medical treatment, the author believes that the management of hypochloremia dehydration and acidosis is most important. Repeated large blood transfusions prove much more effective than saline and dextrose. In addition the author recommends the administration of repeated hypertonic sodium chloride solutions intravenously (50 c.c. of a 9 to 10 per cent solution).

The patient should be operated upon as early as possible once the diagnosis of a mechanical ileus has been established. Many men are reluctant to operate a second time after appendectomy; however the author believes that expectancy involves a much greater risk.

The author has had no experience of his own with the Miller Abbott tube but stated that he believed this method should be tried preoperatively either to remove the mechanical obstruction or if this is not possible to create better conditions for subsequent surgery.

The different surgical methods are discussed in detail. The question whether one should try to visualize and manipulate the obstruction or whether one should confine oneself to a palliative operation (ileostomy) has been answered in different ways. In most cases ileostomy proximal to the obstruction is the operation of choice and gives good results provided the obstruction is not situated so high that there is danger of inanition. Only in rare cases is it advisable to perform at the same time an anastomosis between the ileum and colon.

WERNER M. SOLMITS, M.D.

Conservative or Operative Management of Appendicitis in the Intermediate Stage? (Konservative oder operative Behandlung der Appendicitis im Intermediarstadium?) HEINRICH GÖTTKE. *Chirurg* 948, 9 50.

The present article is interesting particularly from the historical point of view in that the question of the management of appendicitis before abscess formation is still a very serious problem in European countries where antibiotics are unavailable. The author considers the "intermediate stage" that period of about 48 hours following the onset of symptoms (in some cases 3 to 5 days) during which there is the widest variation in the course of acute appendicitis.

A favorable course during this period occurs when the appendix is protected in some way from the rest of the abdominal cavity in which case either an inflammatory mass or an abscess ensues. An uncertain prognosis is given in the cases of those patients with a circumscribed peritonitis which may develop into a mass or an abscess, or may result in a diffuse peritonitis. A poor prognosis is given in those cases of generalized peritonitis which cannot be walled off.

The German literature of the past 20 years is reviewed and three schools of thought are represented. Kneumell, Lexer, Kirschner and Sudeck were advocates of operative management during this stage

of appendicitis except in cases in which a frank walled-off abscess could be palpated. Goette, Reschke and Payr took a middle stand and recommended operation during this stage unless the appendix was ruptured in which event conservative treatment was advocated. The opinions of these authors varied slightly with regard to the time limit. Reschke suggesting 48 hours while Payr waited 3 days. A third school, consisting mainly of Jungbluth and Narath, was considered the conservative group since they operated only on acute appendicitis without perforation leaving all other cases for conservative management.

After an extensive review of the mortality statistics from various European clinics which indicate that the mortality among patients operated upon rises sharply after the first 48 hours, the author arrives at the following conclusions:

Every acutely inflamed appendix should be removed within 48 hours of the onset of symptoms. Between 48 hours and 3 days the therapy varies from case to case. If the appendix is not yet perforated it is removed. If there is an inflammatory mass, this is removed with the appendix. If there is a free-lying appendix with a purulent peritonitis, the appendix is removed and the peritoneal cavity is drained. If there is an inflammatory mass plus a purulent peritonitis local drainage is done and later drainage through the pouch of Douglas. In some of these cases it is possible to remove the inflammatory mass and drain the area in other cases technical difficulties may arise in which instance a completely conservative nonoperative course is followed. Late in the intermediate stage (4 to 5 days) a nonoperative course is suggested. For the clinically late cases of appendicitis with abscess, conservative management is followed. In cases of diffuse peritonitis, operation may be done up to the end of the third day after the onset, after the fourth day conservative management is suggested. Interval appendectomy should be done in from 6 weeks to 3 months after the attack, depending upon the individual pathology.

It is interesting to note that the conservative therapy outlined by this author does not include the use of antibiotics while it does include such questionable therapeutics as peritonitis serum, adrenalin, and intravenous calcium. HANFELD LAUFMAN, M.D.

The Concept, Mobile Cecum, and Its Surgical Management (Der Sammelbegriff "Cecum mobile" und seine chirurgische Behandlung) HERBERT JONASMAN. *Chirurg* 947 7-8 350.

In the past forty years the clinical entity known as "mobile cecum" has acquired a large number of pseudonyms, and no less than 15 surgical procedures have been advocated for its correction. The purpose of this article is to point out by means of a review of the literature as well as by diagrams, the many different varieties of mobile cecum.

The syndrome is usually one of long standing right lower quadrant pain with acute exacerbations on-

accompanied by the usual clinical and laboratory findings which would ordinarily be interpreted as acute appendicitis. In many of these cases the condition is diagnosed as appendicitis only to have the symptoms recur after appendectomy. Aside from the chronic type of pain there are usually audible borborygmi in the right lower quadrant, and a tumor mass can often be palpated. Careful roentgenographic and fluoroscopic studies will usually reveal the type of mobile cecum that is present.

Despite the many varieties of mobile cecum and the many confusing names heretofore applied the author believes that all types should be called simply mobile cecum although the surgical approach to the various types need not be alike. The individualization as far as surgery is concerned will depend upon the pathology presenting itself. Procedures which have proved successful depending upon the type of lesion present, are fixation to the lateral peritoneum, resection of the redundant portion of the cecum or entire right colon, and various types of side-to-side anastomoses, in order to prevent stagnation in the enlarged cecum.

If the surgeon is aware of the various procedures which might be utilized he will then be able to adjust his surgical approach to the pathology presenting itself rather than be committed to a specific surgical procedure in each instance.

HAROLD LAUTMAN M.D.

The Present Day Therapy of Thromboembolic (Streptococcal) Colitis. J. ARNOLD BARON *Med Clin. N. America* 1943, 32: 667

In the present article the author considers that form of ulcerative colitis which has its inception in the most distal portion of the rectum and spreads relentlessly orad from that point.

The author stated that treatment should rest on the convictions (1) that the condition is an infectious disease of the large intestine (2) that uncomplicated cases constitute a medical problem, and (3) that certain complications are definite indications for operation.

Medical management of the patient includes rest and restful recreation, a diet adjusted to the needs of each patient, vitamins, vaccine, nursing care, drugs and antibiotics, oxygen, transfusions of blood, irrigations and instillations, removal of foci of infection and parenteral administration of fluids.

The decision whether an operation should be performed is a common problem in these cases. Certain late sequelae of the disease present definite surgical problems. The principal ones are polyps, neoplasms, strictures, extensive perianal fistulas, localized perforations and abscesses of one kind or another. Except for these and such essential operations as those for acute intercurrent surgical disease, surgical treatment should seldom be used. Ileostomy was found to be the procedure of choice.

When the disease has advanced so far that ileostomy is advisable, colectomy usually should be performed at a later date and as soon as the patient's

condition warrants. In most cases it is well to postpone colectomy at least 6 or 8 weeks after the ileostomy.

Medical management should proceed after ileostomy in the same manner as before the operation and if medical treatment is carried out carefully there will be a few cases in which colectomy will not be necessary and the ileac stoma can be closed with reasonable safety.

The patients without colons can live just as full and happy lives as those who have colons. No demonstrable physical deficiencies follow colectomy. It does not disturb the physiologic equilibrium of the body generally or of the chemical constituents of the blood except temporarily. The terminal portion of the ileum becomes demonstrably although not markedly dilated after colectomy. A general diet can be taken. Special care of the ileac stoma becomes minimal. Patients are able to resume their economic and social activities. The same advice and precautions about overdoing and prevention of nerve tension, given to the patient whose condition is controlled by medical means, apply to all patients who have had thromboembolic colitis. Occupations should be such that undue exposure to the elements and great expenditure of nervous energy are not needed and adequate physical and mental rest can be obtained.

There is analogy between the course of this disease and that of tuberculosis and every patient who has had a severe attack of ulcerative colitis is always a potential colitis patient. Relapses are common if the medical regimen is not followed assiduously. The most common causes of relapse are (1) infection of the upper part of the respiratory tract, (2) mental and physical trauma and (3) the lighting up of distant foci of infection.

Colectomy in Ulcerative Colitis. SIR HUGH DEVINE and JOHN DEVINE. *Brit. M. J.*, 1943, 2: 127

The results of surgical treatment in 11 desperate cases of ulcerative colitis are reported. A stage procedure is described in which each successive step in treatment was designed not only to bring about improvement but also to be a stage in the removal of the colon. An enterostomy was so planned that it was a step in the formation of an ileorectostomy. About 5 weeks later the ileum was connected to the rectum by the use of a special spur-clamp and the open ends of the bowel taking part in the anastomosis were closed under local anesthesia. The colon now isolated with both ends forming two mucous fistulas was completely out of action and was treated by routine chemotherapy over a period of months until the patient ceased to improve. Since there was no discharging enterostomy and the patient was comparatively comfortable, this period could be prolonged indefinitely until the patient was fit for the last stage, namely, colectomy.

In another case the ascending colon showed no evidence of the disease and was preserved and used as an artificial anus while the remainder of the colon

and rectum were resected in stages. Subtotal colectomy was also of value through the removal of much of the diseased colon.

Of the 11 patients, 2 died. One patient died of an adynamic ileus immediately following the first stage modified enterostomy and one died 3 months after the first stage from tissue deficiency and toxemia. None of the patients died following colectomy or excision of the rectum. Six patients seem to be cured and the patient who had the worst case of all has been well for 6 years. They have no discomfort and lead normal lives.

Although the series is small it includes such severe cases and such good results that the authors have built a future surgical policy based upon their experience. They believe that a case of established ulcerative colitis should come to a surgical consultation early in its course to consider the question of early operation from the following viewpoints:

1. Can the surgeon help the physician? He may be able to do so by making a nonleaking valvular appendicostomy.

2. There is some justification for the removal of the appendix since it is not above suspicion as the point of entry of the infective element in the colitis.

3. To find out early in the course of the disease whether or not the ascending colon is free of the disease because in this case the prognosis is much brighter and early operation is justifiable.

4. To ascertain the type and severity of the disease with a view to planning its treatment.

The author believes that judgment as to whether medical treatment will cure or not can be made. More attention to tissue resistance and tissue repair is advised since they probably play a more important part in this infective disease than does the virulence of the organism. When ulceration and loss of substance of the mucosa have taken place and the physician is making no headway with his treatment, early operation with a view to removing the colon is advised. The reward of early colectomy or subtotal colectomy is a low immediate mortality and a good chance that the rectum will recover when the colon is removed. JOHN L. LINQVIST, M.D.

Blastomycosis of the Anorectal Region. Considerations on 2 Cases (Blastomycose da região anorectal. Considerações sobre dois casos). CARLOS DA SILVA LACAY and EDISON DE OLIVEIRA. *Hospital Rio*, 948, 33, 845.

South American blastomycosis improperly called Brazilian blastomycosis, rarely causes manifestations in the anorectal region. The lesions are usually localized in the buccopharynx, the lungs, the skin and the lymph nodes. The portal of entry for *Paracoccidioides brasiliensis*, the agent of the mycosis is generally at the buccopharyngeal or respiratory mucosa exceptionally at the skin. The authors report 2 cases with involvement of the anorectal region. In one of them the condition was probably due to the use of vegetal leaves to cleanse the region after defecation.

In the first case the lesions consisted of perianal ulcerations with elevated and papulous borders and a granular base covered by purulent secretion in which were found forms of the *paracoccidioides*. The rectal mucosa was hyperemic and bled easily. There were two small ulcerations in the middle portion of the rectum. The lungs were not involved. In the second case the only lesion was a small superficial ulcer of the rectum, with irregular contour and covered by purulent secretion. Biopsy revealed the presence of *paracoccidioides*. There was no pulmonary or other involvement. Both patients were treated successfully with sulfadiazine.

The anorectal localization of the disorder must occur more frequently than is generally believed. Only 2 cases have been described in the literature. The intestinal lesions are usually located in the cecocolic region and are of variable size with a granular base and may involve the serosa, with consequent inflammatory reactions and the formation of adhesions. The agent usually causes a granulomatous reaction of diffuse type that starts in the lymphatic follicles and Peyer's patches of the submucosa. A careful proctologic examination should be made in every case of South American blastomycosis because of possible rectal involvement.

Paracoccidioides brasiliensis is found on plants and in the soil. The frequent habit of the Brazilian mestizo to cleanse his anal region with vegetal leaves should lead to an increase of the anorectal forms of the blastomycosis. However there may be other etiopathogenic mechanisms for such lesions. They could occur through direct localization of the previously swallowed parasite or the parasite could reach the perirectal lymphatics through lymphatic dissemination of the process from some other part of the body. Other conditions may favor the localization of the agent in the rectal mucosa, as amebiasis and lesions caused by shigellosis. The diagnosis is not difficult. The parasite is easily found. It has a characteristic morphology especially in fresh specimens. In case of ulcer biopsy is advisable.

Sulfadiazine is the treatment of choice. A blood concentration of 5 to 10 mgm. per 100 cubic centimeters is sufficient to guarantee frank amelioration. The sulfonamide may be applied locally in the form of pulverization or nebulization. Polyvalent antimycotic vaccine therapy is recommended in addition to general medication to increase the organic resistance of the patient. Unfortunately there is as yet no proof of the cure of the disorder therefore a periodic follow-up is necessary for timely attention to possible recurrences. RICHARD KEMEL, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Cancer of the Gall Bladder (Câncer de la vesícula biliar). ARNALDO YODICE y EMILIO ETALA. *Da med.*, B. Air, 948, 302, 366.

This is an analysis of 14 cases of cancer of the gall bladder all except 2 of the patients had an

associated cholelithiasis and in 11 it was of the scar rhou type. The following symptoms predominated (1) pain in 62 per cent, (2) icterus in 69 per cent and (3) palpable tumor in 68 per cent.

Eight of the 14 patients showed calcification of the gall bladder on preoperative roentgen films and laparotomy was not only necessary to confirm the diagnosis of cancer but was of value for prognosis and metastatic studies.

Nine patients were considered inoperable. Three were treated with x-rays and one of these survived 4 years, the 2 others however lived only 7 and 8 months respectively. Of the 5 patients operated upon one lived 2 years and the others lived 15 years 9 months 5 months and 3 months respectively.

Because of the desolate outcome of the 14 cases described it is hoped that the observations given may help to alert others toward an earlier recognition of cancer of the gall bladder.

STEPHEN A. ZIEGLER, M.D.

Considerations with Regard to a Case of Acinous Carcinoma of the Pancreas with Hypoglycemic Manifestations (Consideraciones acerca de un caso de carcinoma acinoso de pancreas con manifestaciones hipoglucémicas anteriores). GUNTHER A. FROMM and EDUARDO F. LASCANO. *Arch. argent. enferm. op. digest.* 1947 22: 425.

Despite the difficulty of proof the authors attempt to show the causal relationship between carcinoma of the head of the pancreas and an associated hypoglycemia with the functional modifications of the central and vegetative nervous system, the liver, the hypophysis and the suprarenal and thyroid glands. It is contended that when such manifestations exist along with a presumed pancreatic affection resort to surgery is indicated with investigation of each element of the Whipple triad or of Wilder's postulates.

A case is reported of a 31 year old patient who, 7 years previously had had icterus and associated choledochal blockage. On present admission the patient was disoriented and confused, later collapsed into unconsciousness, developed convulsive seizures and was referred for neurologic studies. These proved unrevealing, but because gall bladder disease was found on physical examination a laparotomy was performed which revealed a palpable tumor of the pancreas. The tumor which proved to be an acinous carcinoma was removed without incident. The associated extraneous symptoms diminished progressively after removal of the tumor.

It was concluded that the carcinoma created the hypoglycemia, which, in turn, was responsible for the convulsions, facial paresis and the other neurovegetative symptoms. The deranged glycogenic metabolism accounted for the suprarenal insufficiency as well as the hypophyseal and thyroid complications.

MISCELLANEOUS

The Infected Ovarian Teratoma as a Diagnostic Problem (Ueber die infizierten Eierstockteratome als diagnostisches Problem). KEIJO SORITA. *Ann. chir. gyn. jap.* 1948, 37: 80.

The author stresses the fact that infections in dermoid cysts of the ovary are quite rare. In Blackwell and Dockerty's series, infection was present in only 1 of 273 cases while in other series infection occurred in as high as 11 per cent. The author presents 4 personal cases. Three of these lesions were infected dermoid cysts and the fourth was an infected embryonal teratoma. The source of the infection in 2 of the cases was ascertainable. In one case infection followed vaginal aspiration of the cyst and in the second case infection followed typhoid fever. In the embryonal teratoma, the infection might have been ascribed to a puerperal sepsis.

In a review of the literature the author found that in most of the early cases of infected teratoma the infection was introduced by diagnostic or therapeutic aspiration. As this procedure has been discarded the number of infected cysts is also decreasing. A good many cases have been reported in which typhoid or paratyphoid bacteria have been recovered from the cysts. The author's case was such a one. Puerperal sepsis has also been repeatedly reported as a cause of the infection.

The diagnosis of infected cysts is not simple. Its clinical manifestations are almost indistinguishable from salpingitis, tubo-ovarian abscess and suppurative parametritis. The author believes, however, that in many instances the x-ray examination will be helpful. In almost 50 per cent of cases, teeth or bone can be visualized in the skiagram. These must be differentiated from intestinal content, calcified lymph glands, calculi in the urinary tract, and calcified uterine fibroids. They are less frequently observed in older patients which leads to the suggestion that the calcium may be reabsorbed. Further more the content of the typical dermoid cyst may cast a negative shadow. The only other intra-abdominal materials casting a negative shadow are gas in the bowel, cholesterol gall stones and retroperitoneal lipomas.

Some of the authors have called attention to the possibility of seeing lines which suggest the appearance of hair in the cyst. The author has, however, never observed this. In one case a salpingogram was made while a probe was placed in the vaginal sinus. This film gave a definite clue to the diagnosis.

The only clinical sign which may help in the diagnosis is that a palpable mass may be present which is independent of the uterus. This in the presence of the signs of infection may lead one to suspect the presence of an infected dermoid cyst. The only sure method of diagnosis is the exploratory laparotomy.

WILLIAM C. BRICK, M.D.

GYNECOLOGY

UTERUS

Primary Dysplastic Involuting Myofibrosis of the Uterus (*fibroblast primitiva displastica involutiva dell' utero*) PAOLO FORNI. *Ri. Ital. ginec.*, 1948, 31: 58.

The author reports 2 cases of primary dysplastic involving myofibrosis of the uterus in nulliparas (one 27 the other 32 years of age) whose menstruations had been abundant from their inception both patients had developed menorrhagia which caused severe anemia the uterus was uniformly enlarged and subtotal hysterectomy and bilateral adnexectomy were performed

Macroscopically the uterus, although enlarged had practically retained its original form and was markedly indurated. On section the myometrium had lost its normal aspect, but the mucosa seemed to be intact. The increase in volume was due to thickening of the muscular wall and dilatation of the uterine cavity. The myometrium presented an anemic aspect and was of a yellowish color, against which stood out a whitish network of glistening tissue having the appearance of tendinous fibers that grated on cutting. Microscopically there was a more or less marked hyperplasia of the muscular elements (in the first case) and of the fibrocytic elements (in the second case). Their increase seemed to run parallel to the proportions of the two remaining the same all over the uterus. The vascular changes were only secondary and without peculiarities. There were no inflammatory processes, or remnants of such processes and no infiltrates.

From the histologic and histochemical characteristics of the proliferated tissue there was no question of ectotrophic tissue but of a particular type of tissue which assumed simultaneously the aspect of muscle and of connective tissue and seemed to derive from a genotypically vitiated bud. In other words there seemed to be a missed or deviated maturation and differentiation of the primary mesodermal elements which should have produced the muscular elements of the uterine wall and therefore also a rapid degeneration of the newly formed muscular elements with formation of a myomechymal tissue which being more resistant, had determined the increase in volume and later the fibrosis of the uterus. The varying degrees of hyperplasia and of evolution of these elements could thus explain the varying aspects (myohyperplasia sclerosis etc.) which these so-called fibrotic or sclerotic uteri present histologically and also the absence of any signs of previous or actual inflammatory process. Consequently there is here an involuting dystrophic dysplasia of the muscular cells of the myometrium, the picture of which can be found in other lesions of the striated muscles as for instance in cases of congenital torticollis.

The various pathogenic factors advanced by some (particularly pregnancy the menopause, and menstruation, because of the circulatory disturbances which they produce in the myometrium) would thus simply play the role of adjuvant etiologic factors in the determination of the fibrous involution of the uterus. For these reasons the author calls the lesion a primary dysplastic, involuting myofibrosis, representing a well defined entity which may have some aspects in common with fibromyomatosis and, to a lesser degree with fibroma rather than with fibrosis or sclerosis, which terms should be reserved for results of metritic processes. RICHARD KEMMEL, M.D.

Technique of Radium Therapy for Cancer of the Uterine Cervix (Sur la technique de la curietherapie des cancers du col de l'uterus) EMILE WALLON. *Presse med.* 1948, No. 19: 244.

Successful results of radium therapy in cancer of the uterine cervix are largely dependent upon a most precise technique. Lacking this, apparently satisfactory immediate results may be followed by recurrence or serious complications. Failures may be attributable to inadequate dosage exclusively vaginal application, inadequate protection of adjacent tissues and organs or to a secondary radioresistance developing as a result of insufficient treatment. Failures have, however been reported in cases in which no obvious fault in technique could be demonstrated. In such cases, the distribution of radiation may have been interfered with because of difficulty in adjusting the apparatus at onset, or its subsequent displacement. Because of scattering of the rays, the dose received by the tissues may vary widely and some tissues may escape irradiation altogether.

A series of roentgenograms are presented to illustrate the cause of some failures. Thus in some patients with retroversion of the uterus there may be marked infiltration and retraction of the vagina, forcing the end of the tube toward the rectum. Since only a single tube can be inserted the radiation affects too limited an area to produce complete sterilization, and unless it is supplemented by radiotherapy parametrial recurrence may be expected.

Destruction of tissue may also lead to displacement of the radium containers with resulting irregular distribution of the rays. In some cases there is a tendency of the tube to slip out of the uterus, and unless a control roentgenogram is taken, the operator believing the apparatus to be in the correct position, might have delivered the usual dose with resulting rectal complications. The tube may also be displaced by the colpostat which leads to overdosage or inadequate dosage according to its location. Overdosage to one of the lateral cul-de-sacs owing to displacement of the apparatus may cause injury to the ureter. Without routine roentgenologic control, it is difficult to know whether the radium treatment has

been satisfactory. Errors detected by this method can be rectified as a rule but in some cases errors defy detection as, for instance, in cases of neoplastic fixation of organs in abnormal positions. However roentgenologic examination is useful also in these cases since by indicating areas insufficiently treated the latter can be reached by roentgen therapy.

Radiologic control will permit a more precise study of the exact cause of failure in certain fatal cases. Before concluding that a tumor is radiosensitive it is necessary to ascertain that the radium is properly placed.

EDITH SCHANCHER MOORE.

Reticuloplasmosarcoma of the Uterine Cervix
(Sul reticuloplasmosarcoma del collo uterino)
FRANCESCO SERA. *Quad. clin. anat. gin.*, 1948 3 191

A 49 year old woman had been suffering for a year with a fetid leucorrhea and of late had had severe pains in the lower abdomen. At the Cancer Institute of the Vittorio Emanuele Hospital in Catania Italy, the cervix was observed to be markedly swollen and indurated and covered with reddish-gray easily bleeding vegetations. The Wassermann reaction was negative even following reactivation.

A biopsy was done and the histological examination of the specimen disclosed a mass made up of reticular tissue with a predominance of plasma cells, with a pronounced pyroninophilia (Pappenheim) of their protoplasm. Some of these cells were smaller and resembled histiocytes however these also were pyroninophilic and were classed as immature plasma cells or preplasmocytes. Some of the cellular elements of the reticular component were also quite large with at times two or more nuclei. All these elements showed a tendency to group themselves about the numerous blood vessels which however showed no indication of syphilitic changes. Many cells of all types exhibited mitotic figures.

It is believed that the tumor in this case was of a sarcomatous malignant character arising from the reticular tissues and exhibiting a tendency to develop by metaplasia into plasma cells. It is also thought to be the first tumor of its type in this location which has thus far been reported in the medical literature. The findings in this case confirm the author's belief that the plasmocytoma is often confused with chronic vegetative masses about the feminine genitalia which are of syphilitic or gonorrheal origin and that the true plasmocytoma is in itself very rare in this location.

JOHN W. BRENNAN, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Microscopic Studies on Chocolate Cysts. A Contribution to the Etiology of Intraperitoneal Endometriosis (Mikroskopische Studien an Schokoladenzysten. Ein Beitrag zur Ätiologie der intraperitonealen Endometriose) VOZOK. *Geburtsh. und Frauenh.*, 1947 7 48, 87

The etiology of chocolate cysts has been a controversial subject in the literature for many years.

Most authors adhere to the implantation theory. The fact that these cysts occur most frequently in the ovary supports this theory, small particles of endometrium tissue are carried back with the menstrual blood to the ovary when, for some reason or other the outflow through the cervix is impeded.

However, many authors have been unable to find endometrial tissue in histologic examinations of chocolate cysts. Experienced gynecologists like Philipp and Huber believe that in only 60 per cent of cases are these cysts caused by endometriosis and that in many cases they occur as the result of a primary hemorrhagic diathesis in the capillaries.

The author examined a series of 50 chocolate cysts histologically and was able to find endometrial tissue in every one of them. He believes therefore that implantation of displaced endometrium is the sole cause of chocolate cysts. He discusses the technical difficulties in finding the endometrial tissue especially in large cysts and believes that the wall of the cyst should be examined in fresh condition, immediately after the extirpation. The cysts are never entirely surrounded by a membrane and usually there is a defect at the posterior wall. It is in this area that endometrial tissue is most likely to be found.

The reaction of the endometrial tissue in the cysts to the ovarian hormones varies in the individual cases. If the tissue is walled off by ovarian stroma, muscle fibers or connective tissue it is not influenced by the hormonal cycle but remains in the proliferative stage. If, on the other hand the endometrium grows toward the cavity of the cyst, it shows the same cyclic changes as the endometrium of the uterus.

With regard to the etiology of external endometriosis the theory of Philipp and Huber is that all cases of chocolate cysts are due to endometriosis in the fallopian tubes. The author examined 27 patients with chocolate cysts in the free abdominal cavity at a loop of the ileum or at the appendix. In only 4 of these was he able to find endometrium in the tubes although the entire length of both tubes was carefully examined by serial cuts. He believes therefore that in most cases external endometriosis also is caused by uterine tissue which has been washed back with the menstrual flow.

Thecoma of the Ovary and Carcinoma of the Endometrium (Tecoma del ovario y carcinoma del endometrio) JUAN CARLOS ARUMADA, RODOLFO SAMAMITINO and JUAN L. SARDI. *Obst. gin. lat. amer.*, 1948 6 34.

Three cases of thecoma of the ovary associated with carcinoid proliferation of the endometrium are presented. The query proposed is whether there is a direct causal relationship between the two conditions or they are coincident and coexistent findings. No positive position is taken however certain inferential conclusions are given such as the relative frequency of thecoma of the ovary and atypical

hyperplasia of the endometrium and the effects of thecoma of the ovary on the postmenopausal uterus.

In many instances the small size of a thecoma of the ovary may cause it to be overlooked during a gynecologic examination.

EXTERNAL GENITALIA

Vaginal Autodepuration. Present Status of the Problem and Its Possible Development: The Biologic Significance of Lysozyme in the Vaginal Secretions (L. todepurazioe vaginale. Stato attuale del problema e suoi possibili sviluppi, significato biologico del lisozima nell'umore vaginale) G. VACCINETTI. *Quad. clin. del gin.* 1943, 3: 73.

In the study of Fleming's lysozyme an attempt is made to develop a reliable method of estimating quantitatively the amount of lysozyme present in the various body secretions, excretions and fluids available to a gynecologist. The method used at present is a modification of that of Sherwood, Falco and DeBeer for the estimation of penicillin dosages. The use of inverted cylinders over a culture in agar as developed by the Oxford workers with penicillin, is rejected as too full of inaccuracies for quantitative work. At present the method used is based on the cutting of small holes in the surface of the agar plate and the insertion of the material to be tested in these small wells. The organism employed for these agar plate cultures has been the *Micrococcus lysodeikticus* which is extremely sensitive to the lytic agent.

With use of the author's method it has been determined that many of the body fluids and substances contain these lytic enzymes—enzymes in that they are not used up in the process of carrying out the lysis. They are present in greatest concentration in the human being and to a lesser degree in animals. Even certain plant constituents contain them. Most interesting is their presence in great quantities in the albumin of the egg. In the realm of gynecology and obstetrics they are found in the amniotic fluid, in the funicular blood, and in the vaginal secretions. It is this latter finding which the author tries to fit into the vast and complicated picture of vaginal depuration.

The lysozyme was found in all the secretions of the vagina. It was present in very high concentration in the protective cervical mucous plug and the amount became less in the lower regions of the vaginal tract, but even at the outlet it still showed considerable activity. In the vagina of the newborn infant, Fleming's lysozyme is already present in small amounts which increase notably by the fifth to the seventh postnatal day until in the adult, the amount normally reaches the level of 1,600 to 51,300 U.g. (units of lysozyme per gram of material). In the present study it was not affected by the state of the vaginal pH nor by the presence of other bacterial strains in the vagina. The titer always seemed to increase in the presence of inflammatory conditions in the cervix or vagina. During menstruation the

values usually dropped to 25, up to 75 U.g., except in one instance of exocervicitis in which the titer remained at 1,600 U.g. Following the menopause also the titer dropped but remained at a moderate level. During pregnancy the titer was high and remained at the usual level during the puerperium. In the dysfunctional menometrorrhagias the levels were low and in tumors of the portio and corpus uteri the amounts varied but they were always higher in the presence of inflammatory complications.

The characteristics of the lysozyme could be easily distinguished from those of the bacteriophages and from the lytic principles of Gengou, of Turro, and of Petterson. The presence of penicillium notatum, the lytic action of associated bacteria on the *Micrococcus lysodeikticus*, and any antilysozymic activity as the explanation of lysozyme resistance in some of the associated organisms could be excluded.

From the author's own experiences and from his study of the literature he concludes that the lysozyme present in the vaginal secretions acts as a valid defense against the microbial increments in the lower levels of the genital tract of the normal, healthy human female.

JOHN W. BRIDGMAN, M.D.

Vaginitis Emphysematosa. HERMAN L. GARDNER. *Am. J. Obst.* 1943, 56: 3.

Of such rarity is the condition variously known as vaginitis emphysematosa, colpohyperplasia cystica, and emphysematous colpitis that it might well be placed within the realm of medical curiosities. The author presents a case report of vaginitis emphysematosa, giving full microscopic and gross details of the condition.

The characteristic lesion is one of gas-filled cystoid cavities of the mucosa and submucosa of the vagina and cervix. The lesion usually involves both the upper vagina and the cervix, but occasionally is limited to one site or the other. Vaginitis emphysematosa is more often seen during pregnancy. The condition is productive of only mild (if any) symptoms. The point of greatest interest concerns its etiology and this remains obscure. Although several theories have been formulated as to its development, none seem acceptable to our present-day pathologists with their increased knowledge of causes and the pathogenesis of diseases. Some possible stages in the pathogenesis of vaginitis emphysematosa are suggested. Argument is presented to support the opinion that the gas within the lesions has an endogenous origin as opposed to an assumption that the gas is air.

JOHN R. WATTS, M.D.

Abdominal Colpocystostomy for Complete Prolapse of the Vagina and Bladder. PAUL F. FLETCHER. *Am. J. Obst.* 1943, 56: 41.

The author submits the "rectus suspension principle of crossed-suspender support" as a dependable surgical procedure in the treatment of complete prolapse of the vagina and bladder following hysterectomy for patients in whom an abdominal operation is not contraindicated. The important factor in-

volved in complete prolapse of the vagina pertains to the complete eversion of the anterior vaginal wall and bladder. It is the correction of this condition with which the author is primarily concerned.

The technique and operative procedure are described in detail, and illustrated. The preparation and mobilization of the vagina and bladder are shown. The author utilizes the Moschowitz technique of closure of the cul-de-sac for the prevention or correction of a hernia of the posterior vaginal wall.

Mobilization and placement of fascial strips from the anterior rectus sheath are performed so that the strip is long enough to reach the ureterovesical junction on the opposite side when the bladder is distended.

The location of the point at which the strips cross each other is decidedly important, because this is the point at which the greatest amount of support to the bladder is rendered. It should be situated on the interior aspect of the bladder wall as close to the posterior border of the trigone as it is conveniently possible to get it. This is facilitated by taking the strips from the anterior sheaths of the fascia rather than from the medial borders. Although it causes the 'crossed-suspender' effect to be rendered at a slightly wider angle, the point of greatest support to the bladder is more efficiently located.

Postoperative treatment is routine except that continuous bladder drainage is maintained for at least 6 days. When drainage is discontinued careful precautions must be taken to be sure that subsequent overdistention does not occur.

The operation was performed for the first time more than 7 years ago. A summary is given of a series of 7 cases in which this principle has been used for the treatment of complete prolapse of the vagina and bladder following hysterectomy.

MISCELLANEOUS

The Restorative Operation Following Sterilization
(Die Wiederherstellungsoperation nach Sterilisation)
H. SCHMIDT ELMENDORF. *Geburtsh. & Frauenk.*
1948, 8, 301

The authors group sterilization operations into three types: (1) the excision of varying portions of the fallopian tube; (2) burying the end of the tube in the abdominal cavity by enclosing it in a fold of peritoneum; and (3) removal of the entire tube. About half of their patients were sterilized by the burying of the tubal end in the abdominal cavity.

The authors have devised an operation to restore functional continuity of the tube and uterus which is essentially as follows:

The abdominal (proximal) end of the tube is freed and any stenotic portion is removed. Three 0.5 cm long equidistant, splitting incisions are made through the entire thickness of the tubal walls and a ureteral cannula is threaded through the lumen of the tube. Through an incision in the posterior wall of the uterus the cannula is introduced to lead the split end of the

tube up to the uterine cavity. The split ends are folded back on themselves and tacked to the serosa of the uterine incision. The catheter is led through the uterine cavity and vagina and fixed externally during the postoperative period. This technique tends to reduce cicatricial contracture and stenosis of the tube.

In order that this operation may be done the tube itself must be intact; there must be an adequate blood supply to the tube and operative compression must be avoided. The best results are obtained in patients who have not had previous infection of the pelvis.

Four of the 9 patients have later become pregnant.

In 10 of the patients in whom the tube has been removed or cannot be reconstructed the authors have made an ovarian implantation into the wall of the uterus. The results of this type of operation are not remarkable. Even if functional ovulation is restored as evidenced by regular menses rarely do fecundation and pregnancy ensue. This may possibly be due to the fact that the ovum does not have a protected course en route to the nidation site or it may be possible that the uterus changes postoperatively so that it becomes unsuitable for nidation. In the literature only 12 of 240 patients with an ovarian transplant into the uterine fundus have had successful results, and of these 4 or less than 1 per cent of the total have given birth to living children.

JANE C. MACMILLAN, M.D.

Fundamental Operative Methods of Repair of Urinary Fistulas in Women (Metodi operatori fondamentali di riparazione delle fistole urinarie nella donna). CARLO COLOMBINO. *Urologia*, 1948, 15, 99

The vaginal route of repair of urinary fistulas may be employed in the majority of cases, while the employment of the combined extraperitoneal suprapubic and vaginal approach is recommended chiefly in presence of adhesions to the anterior pelvic arch. The transvesical route belongs to the domain of the urologist. In difficult cases, especially in patients who have previously undergone surgical interventions, a two stage operation is recommended by the author: the first stage consisting of suprapubic cystostomy for derivation of the urine.

The author favors Schuchardt's incision because it facilitates access to the lesion.

In the postoperative treatment the importance of the retention catheter is stressed in addition to the use of sedatives for the purpose of immobilization of the patient during the first few postoperative days. Prophylactic use of urinary antiseptics and daily irrigations of the bladder with mild mercurial solutions are recommended by the author. Periodic examination of the operative regions are made starting on the third or fourth postoperative day. As a rule, the retention catheter is removed on the twelfth day.

In a case with complete destruction of the urethra an interposition of the uterus furnished good results.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Serum Beta-Glucuronidase Levels during the Toxemia of Pregnancy LISTER D ODILL and DONALD F McDONALD *Am J Obst* 1948, 56 74.

The purposes of this report are (1) to emphasize the differentiation by serum beta-glucuronidase values of pre-eclampsia and hypertensive toxemia of pregnancy (2) to illustrate the use of beta-glucuronidase levels in detecting a potential pre-eclampsia (3) to point out that beta-glucuronidase values are apparently of no prognostic value (4) to report levels for convulsive toxemia of pregnancy (5) to illustrate examples of toxemia of pregnancy in which repeated serum levels of enzyme were obtained and to correlate these with the clinical course of the disease.

Although the upper range for normal pregnancy does not exceed 17.5 micrograms per cubic centimeter at term, with few exceptions serum beta-glucuronidase values were high during pre-eclampsia. In fact, a figure above 20 micrograms seemed diagnostic for this condition. In patients with hypertensive toxemia most levels were within the range for normal pregnancy. Several patients were observed as long as 5 months without an elevation of serum beta-glucuronidase.

The authors summarize 5 cases in which the patients had convulsions. The serum beta-glucuronidase levels were not elevated during all the cases of convulsive toxemia of pregnancy.

Forty five patients exhibiting an abnormal weight gain were selected at random after 28 weeks of pregnancy and from one to four serum beta-glucuronidase levels obtained at intervals of every 1, 2, or 3 weeks. Consistently higher values were found in patients developing pre-eclampsia.

From the results of this study it would seem that serum beta-glucuronidase levels could be used to differentiate pre-eclampsia from hypertensive toxemia, but of possible greater importance would be its use to delineate those patients with excessive weight gain who are destined to develop pre-eclampsia from those who are not. Serum beta-glucuronidase determinations, obtained at 3 week intervals, after 28 weeks gestation might warn the obstetrician previous to such an eventuality.

The Effectiveness of Various Diuretic Agents in Causing Sodium Excretion in Pregnant Women. WILLIS L. BROWN and J. T. BRADSHAW *Am J Obst.* 1948, 56.

The concept that edema may be due to a disorder of sodium metabolism has gained popularity to the extent that the clinical management of toxemias of pregnancy now generally includes a reduction in sodium intake. Because of the interest in sodium and in the factors involved in augmenting its excre-

tion a series of studies was undertaken to investigate the effects of so-called diuretic agents on the fluid and sodium excretion in women with normal and toxemic pregnancies.

The authors found that diuretic agents vary in their ability to increase the excretion of water or sodium, or both. Some preparations which are popular as diuretics, such as urea and hypertonic dextrose, were shown to be ineffective in that they did not increase the output of urine.

There seems to be a slight increase in volume of urine and in sodium excretion, induced by adequate amounts of ammonium chloride. The continued administration of ammonium chloride over the second and third days, after an increased sodium excretion has been obtained is relatively ineffective.

Mercurial and xanthine diuretics cause a moderate increase in urinary volume and the most marked increase in total urinary sodium of any of the agents studied. This effect can be obtained with either the mercurials or aminophylline but, from the pharmacological point of view, there seems to be little advantage in combining the two as in the commercial compounds.

Three patients with moderately severe toxemia were studied with regard to both sodium and urinary excretion. While these studies are too few to be of any clinical value, it is of interest that apparently the toxemic patient handles water and sodium in a manner similar to the normal pregnant woman, and responds in a similar fashion to diuretic agents. The evidence available suggests that the mercurials and xanthines are worthy of clinical trial in the management of the toxemic patient.

The clinical management of toxemic patients generally includes a liberal use of sedatives, such as morphine. If observations of the antidiuretic effect of morphine are confirmed its use in patients with oliguria may need to be restricted.

Acute Leukemia and Pregnancy (Leocemia aguda y embarazo) JULIO BARÁN FRANCISCO A. VIANCA IMAS, y JORGE ALBERTO FERNÁNDEZ. *Obst. ginec. sur* 1948, 6 145.

In reporting a case of acute leucemia and pregnancy the authors observed that this was the first instance of this disorder at the Maternity Institute, Buenos Aires, in 120,000 admissions. Furthermore they were able to collect only 83 such cases in the world literature.

Their patient was a 24 year old Italian woman, 2 para IV, who was in the fifth month of pregnancy when she suddenly became prostrate and complained of headache, chills fever vomiting enterorrhagia, and showed ulcerous necrotic lesions in the mouth. Clinical and laboratory studies established the diagnosis. The course of the disease was rapidly downward.

despite interruption of the pregnancy the patient dying 2 5 months later

The authors bring out the necessity of differentiating between acute leucosis and leucemia the latter being malignant and irreversible When associated with pregnancy it has 100 per cent maternal and 60 per cent fetal mortality Interruption of the pregnancy apparently has little influence upon the course of the disease

STEPHEN A. ZIEGLER M.D

Pregnancy and Fibroma (*Grossesse et fibromes*) G. GEXKART and R. VOKAER. *Bruxelles méd.*, 1948, 25 765

Opinions as to the significance of fibroma in pregnancy vary widely some authors consider their presence a catastrophe and others believe that pregnancy is not seriously affected except in rare instances. Also statistics relating to the incidence of fibroma in pregnancy vary widely—from 1 case of fibroma in 1 000 pregnancies to 50 per cent of cases. The authors believe the incidence to be around 1 in 100 cases

Following a brief discussion of the pathological anatomy of fibroma the authors proceed to consider the effect of pregnancy on fibromas It is estimated that during pregnancy about 18 per cent of fibromas undergo red degeneration, an aseptic process with local hemolysis. Changes in size of the fibroma have been noted (usually hypertrophy which occurs chiefly in the interstitial fibromas during the first months of pregnancy) Attention has been drawn to a not infrequent regression of the tumor during pregnancy Also displacements of the tumor may occur the anterior myoma ascending more frequently than the posterior Torsion of the pedicle of the fibroma is less common and usually it is associated with axial torsion of the uterus. It is the sessile rather than the pedicled tumors that undergo torsion and usually before the fifth month. Finally a fibroma of some weight may cause a retroversion of the uterus which may lead to incarceration of the pregnant uterus.

As regards sterility it appears that the interstitial and, in particular, the submucosal fibromas are chiefly responsible As to relative sterility it must be stated that mechanical obstruction leading to abnormal implantations of the ovum renders expulsion of the fetus twice as frequent as in normal implantations because of death of the poorly implanted ovum compression by the tumor incarceration of the uterus or submucosal hemorrhage

The literature on the subject of fibroma as a cause of sterility is reviewed. A case is reported in detail in which, in spite of most unfavorable conditions imposed by the tumor conception took place with normal pregnancy and delivery at 8 months of a macerated hydrocephalus Fibroma is very rarely the cause of ectopic pregnancy It is especially low tumors that lead to abnormal placentation or mal presentation.

Labor especially is likely to be unfavorably affected by the presence of a fibroma. Multiple tumors may interfere with uterine contractions or even lead to

uterine inertia Most authorities agree that the site of the tumor is the determining factor in the obstruction of labor although Stoeckel insists that its size is the important factor Low fibroma, such as fibroma of the cervix or prolapsed subserosal fibroma, may render delivery impossible.

A case is reported of rupture of the uterus with expulsion of the fetus into the abdominal cavity in a case of fibroma of the inferior segment on the right lateral surface of the uterus The woman recovered following a subtotal hysterectomy Rupture of the uterus always results in death of the fetus and nearly always of the mother as well Severe hemorrhage is the rule except in cases in which the vessels are thrombosed. The rupture may be asymptomatic, as in the case mentioned During delivery the fibroma may be the cause of severe hemorrhage or it may interfere with normal detachment of the placenta.

During the puerperium one may encounter, besides the usually rapid atrophy of the tumor a large percentage of uterine infections aseptic degenerations or abundant hemorrhage These secondary hemorrhages are rare

At present most authorities agree that unless signs of complications develop it is preferable not to interfere surgically for fibroma during pregnancy Bonafos and Rouxel (1941) even reported a case of non intervention with favorable results in which the fibroma had become gangrenous during the course of pregnancy However surgical indications must be based on the parity and age of the patient as well as the size and number of the tumors. Some authors recommend routine myomectomy, others perform this operation whenever it is feasible They contend that hemorrhage can be avoided by careful technique and that the state of pregnancy facilitates enucleation of the tumor Delivery is nearly always normal in these myomectomized women and interruption of pregnancy is required in only 10 to 20 per cent of cases. The maternal mortality rate is only 2 per cent. Others advise against this operation.

At term, in the presence of complications all agree that surgical intervention is indicated. Some perform a cesarean section followed by hysterectomy

Since the advent of the sulfonamides and antibiotics, more conservative measures are perhaps justifiable Some authors perform a myomectomy

During labor intervention is not indicated unless the patient is suffering from intra-abdominal hemorrhage or the tumor presents an obstacle to normal presentation The first operation is always a cesarean section followed by myomectomy If the fibroma is subperitoneal or by hysterectomy if the tumor is interstitial or in case of multiple or voluminous tumors. Some surgeons always perform a hysterectomy believing that enucleation with the risk of infection and hemorrhage is too dangerous.

During the puerperium, hysterectomy is indicated for necrotic degeneration of the tumor and myomectomy for hemorrhage A case is reported of pregnancy complicated by a low fibroma, in which the pregnancy went to term, and a forceps delivery was

accomplished with excellent immediate results. A month later the patient was admitted to the hospital as an emergency case in a severely anemic condition owing to profuse hemorrhages. An intramural myoma the size of an orange was removed. The operation was followed by complete recovery. In this case the absence of hemorrhage during pregnancy with the sudden onset of hemorrhage one month after delivery was the point of interest.

EDITH SCHWARTZ MOORE.

LABOR AND ITS COMPLICATIONS

Methods of Management and Results in Primary Uterine Inertia (Ueber die Behandlungsmöglichkeiten und Ergebnisse der primären Wehenlosigkeit: Inertia Uteri) VIILJO TUURILA. *A. n. chir. gynæc. fenn.*, 1945, 37, 137

The author relates his findings and conclusions in 769 cases of primary uterine inertia occurring during the period from 1935 to 1946 in the Second Women's Clinic at Helsinki. Over 60 per cent of the patients were between 20 and 30 years of age. Nearly 80 per cent were primigravidae and of these more than a third were elderly primigravidae, i.e. over 30 years old. Breech presentation occurred in 2.5 per cent of the patients studied. The average duration of labor was 50 hours, 3 minutes, but if calculated from the onset of regular pains it was 38 hours 5 minutes.

The membranes ruptured spontaneously in 406 cases in 318 cases artificial rupture was performed and in 45 instances the records were not complete.

In 270 of the 406 cases in which spontaneous rupture occurred the author analyzed the effect on labor when rupture took place during the first or second stage of labor. In 103 of this group (71.5 per cent) labor improved. In those cases in which the uterine contractions did not increase after rupture of the membranes the average duration of labor was 57 hours and 33 minutes; the average duration of regular pains was 43 hours and 42 minutes; the average time from the onset of labor until rupture was 21 hours and 42 minutes; the average time from rupture until delivery of the child was 35 hours and 50 minutes. The corresponding averages for the cases in which labor was accelerated were 50 hours and 51 minutes, 38 hours and 30 minutes, 42 hours and 20 minutes and 12 hours and 31 minutes, respectively. It is thus evident that the salutary effect of spontaneous rupture of the membranes is most apt to be evident when it occurs late in labor.

When the membranes were ruptured by the obstetrician labor was accelerated in 56 of 38 cases (83.1 per cent). The time intervals in which labor was expedited were 47 hours and 37 minutes, 36 hours and 20 minutes, 41 hours and 5 minutes and 6 hours and 35 minutes respectively. When there was no acceleration the figures were 54 hours and 50 minutes, 40 hours and 58 minutes, 36 hours and 41 minutes, and 13 hours and 51 minutes respectively. Hence it is wise to postpone artificial rupture until late in labor.

Thymophyllin was employed in 114 cases, and in 95 cases (83.3 per cent) a favorable effect was noted. Various doses were administered, but an average total dose of 0.75 c.c. was found necessary for good results. There seemed to be little correlation between the time of administration and the shortening of labor. In 34 patients receiving thymophyllin operative delivery was later required because of uterine exhaustion.

Pituitrin was effective in all 9 patients in which it was utilized. Quinine aided labor in only 10 (54.3 per cent) of 41 patients in whom it was used.

Operative intervention (excluding episiotomy, artificial rupture of the membranes and manual extraction of a breech) was obligatory in 234 patients (30.4 per cent)—103 (31.9 per cent) of the 605 primigravidae and 41 (25 per cent) of the 164 multigravidae were delivered by operative means. Forceps deliveries of which nearly one-half were midforceps, cesarean section, and accouchement forcé, were the most frequent means of operative delivery.

Puerperal morbidity developed in 214 patients (27.8 per cent). The most frequent cause was a mild variety of endometritis. The highest per cent of morbidity in the deliveries accomplished by operative means followed forceps delivery (56 of 112 or 50 per cent).

Two mothers (0.56 per cent) and 33 children (4.3 per cent) did not survive. High forceps were accompanied with an infant mortality of 11.6 per cent.

The general prognosis of uterine inertia is not favorable especially so far as the infant is concerned.

WALTER R. LAMB, M.D.

Cesarean Section in Detroit During 1945: A Comparison with 1925 and 1934. HASLOE C. MAX and R. S. SODALL. *Am. J. Obs.*, 1948, 56, 60.

In Detroit, during 1945, among every 37 births there was one cesarean section. In 1935 there was 1 cesarean section in every 217 deliveries, and in 1925, 1 in 167 deliveries. On the other hand the maternal mortality with cesarean section in the three series was 13 per cent in 1925, 4.4 per cent in 1935, and only 0.8 per cent in 1945. The fetal death rates for the same years were 11 per cent, 12.8 per cent, and 7.8 per cent. By 1945, low cervical section had become the operation most frequently employed since it had proved to have distinct maternal advantages over the classical operation. Cesarean hysterectomy and extraperitoneal section were performed in 4 cases without mortality.

A rise in hospital confinements during the 20 year period to more than 94 per cent of the deliveries in 1945 was accompanied by a reduction in the general maternal mortality to 1.6 per 1,000 live births.

In view of the markedly increased incidence of cesarean sections on the one hand and the greatly decreased mortality on the other the author believes it would be well to consider if too many operations of this type are now being done or if too few were done before. There is evidence that, in 1945, many sections were performed on slight indications, to say

the least. Apparently there is widespread disregard of the fact that although the death rate is low surgically speaking it represents a high immediate obstetric risk as well as a definite hazard in future pregnancies. On the other side of the question it is noteworthy that in 1945 at least 30 of the 58 maternal deaths were believed to have been preventable a number of them by timely cesarean section. Both sides of the question then seem to involve a proper regard for established indications and contraindications. Specifically pointing the way to further improvement is the fact that in at least 4 of the 8 cesarean deaths in 1945 the fatal outcome was due largely to faulty judgment or management.

The fetal mortality rate of 7.8 per cent in the 1945 cesarean sections though definitely better than in previous years, is still twice the over all death rate for infants during the first year of life. The fact that 36 per cent of the infants were stillborn again emphasizes the fact that cesarean section does not necessarily offer the best chance for a living child. Hence there is no justification for undue extension of the use of cesarean section for purely fetal indications.

MISCELLANEOUS

A Contribution to the Study of Conglutination of the Uterine Cervix (Contributo allo studio della conglutinazione del collo dell'utero) S. RIBONI *Fed gyna Genova*, 1948, 43, 63

The 2 cases of conglutination are here reported not only because of the peculiar circumstance that this rare condition (1 in 5,000 or 6,000 deliveries) occurred twice within a week's time but also because of the striking differences in pathology and in therapeutic indications. Conglutination at the external cervical orifice occurred in a 24 year old primipara who had always menstruated normally and nothing abnormal was noted during the pregnancy and even at the onset of labor. After the labor had been in action for 30 hours and the cervix was fully effaced it was noted that the cervical os was still closed and apparently occluded and obstructed by a whitish plug of a substance of greater firmness than the surrounding tissues. A moderate amount of pressure by the examiner's finger was sufficient to force the occlusion, whereupon the uterine orifice immediately spread apart with the appearance of the bag of waters. After a rather slow labor a living female child of 5,500 gm. was extracted with the forceps.

The second patient, a 38 year old gravidula, had undergone a forceps delivery of a dead child. During the present pregnancy a flat pelvis (conjugata vera 9.2 cm.) was demonstrated but nothing abnormal was detected about the cervix. Here, as in the first delivery premature rupture of the membranes occurred and a subsequent fetal asphyxia forced immediate cesarean section. The child was eventually resuscitated however preservation of the uterus seemed indicated in this doubtful period to preserve the procreative power of the mother. The lower

portion of the amniotic sac about the internal cervical orifice was adherent to the uterine wall and the internal os itself seemed to be conglutinated. The operator's finger inside the uterus could be forced part way through the cervical canal and then a curved forceps was forced the rest of the way through into the vagina and the tract thus formed was dilated. Subsequently upon vaginal examination it was found that the forceps had deviated from the canal and forced a false passage behind the true cervical opening. The lip of the cervix was then grasped by a tenaculum and a straight forceps was forced along the true cervical canal which was thoroughly dilated. This opening was considered adequate for drainage, although there was a huge clot in the uterus resulting from a partially detached placenta. The contents of the uterus was foul. The patient had manifested a fever during the period of delivery. The peritoneal cavity was dusted with sulfonamide a sulfonamide-gauze drain was left in the uterine cavity, and the administration of penicillin was started. Recovery was uneventful.

The author believes that with the new surgical aids hysterectomy is no longer indicated in these cases of conglutination if adequate drainage can be assured through the cervix.

JOHN W. BRENNAN MD

Peritonization of the Lesser Pelvis with Vesical Peritoneum and Its Obstetrical Consequences (La peritonisation du petit bassin avec le péritoine vésical. Ses conséquences obstétricales) G. CORRI: and J. MATHIEU *Rev fr gyna obst* 1948 43, 13

In most conservative operations on the adnexa, the vesical peritoneum is left intact and can be used to cover the raw surfaces of the uterus and parametrium. In cases in which only the ovaries and uterus can be preserved and therefore with no possibility of pregnancy the uterus may be completely hooded by the flap which is sutured to the peritoneum to cover the uterine isthmus and uterosacral ligaments. If the base of the cul-de-sac of Douglas has likewise been denuded it too can be covered by excluding it with a suture of the vesical flap to the anterior surface of the rectum. To prevent fresh adhesions to the ovary it is always left above this level in a peritoneal cavity with normal walls. After experience with this intervention for 25 years the authors conclude that with this technique they can prevent the majority of failures attributed to conservative operations for adnexitis.

However in cases of only unilateral castration and of myomectomy the uterus cannot be brought into so accentuated an anterior position as attempted in the cases mentioned. Generally speaking it would seem wise not to pass beyond the utero-ovarian ligaments posteriorly. It is even suggested that the end of the vesical flap be sutured on the sides to this ligament which leaves the tube quite free. However if raw surfaces remain on the side from which the adnexa have been removed, these may be excluded by suture of the vesical peritoneum farther posteriorly

on this side. Possibly following cicatrization there may be some torsion of the uterus on its axis, which might be responsible for the obstetrical complications recently described as a result of this method by Gonnert. Hitherto no such complications have been reported. During the past 3 or 4 years, however several cases of dystocia in patients previously subjected to vesical peritonization have been reported. In Gonnert's series of 96 cases of pregnancy following vesical peritonization, 90 per cent of the patients were normal. The incidence of complications during pregnancy was no greater than in nonoperative cases. The incidence of abnormal presentations was, however 9 per cent as compared with 0.3 per cent in nonoperative cases. These were chiefly shoulder presentations. In such cases, labor does not begin normally and if it is not induced the fetus may even die in utero. Cesarean section is the only suitable procedure and should be done promptly to save the life of the infant. In operations performed on such patients it was frequently observed that the uterus was in a position of left or right torsion with the adnexa accordingly forward. The bladder most frequently had moved upward on the anterior surface of the uterus completely covering the inferior segment, so that hysterotomy was usually preferable to low cesarean section.

The authors have attempted to discover the mechanism responsible for these abnormal presentations. In 10 of the cases reviewed in which Gonnert attributed obstetrical complications to vesical peritonization there were associated factors which would have to be considered. Thus in 3 cases there was a narrow flat pelvis, in 3 other cases, uteroparietal adhesions and in 1 case there was low insertion of the placenta. Any of these conditions might have contributed toward the abnormal presentation. It was also believed of interest, in attempting to evaluate the role of vesical peritonization in these complications, to ascertain the type of the previous gynecologic intervention. It was noted that although abnormal presentation occurred in 3 cases in which the Pentaloza peritonization had been done for correction of

retrodisplacement, in 20 other cases in which there had been no myoma or adnexitis the pregnancy and delivery were normal, including a case in which the peritoneal flap had been sutured in back of the uterosacral ligaments (with a subsequent normal pregnancy). In only 3 of 30 patients with peritonization following unilateral castration were there subsequent pregnancies with abnormal presentations. The incidence of the latter following myomectomies was slightly higher probably because of the uterine contraction. In patients who became pregnant after peritonization for extrauterine pregnancy and colometriosis of the isthmus deliveries were normal. Therefore, the incidence of abnormal presentation following the Pentaloza procedure is from 6 to 7 per cent.

The high incidence of shoulder presentations is attributed by the authors to faulty technique, namely to the fact that during peritonization the bladder has not been adequately liberated from the vesical peritoneum, which permits the bladder to rise, frequently half way up the pregnant uterus, as demonstrated by the adhesion of the bladder to the wall of the uterus. Bertrand and Roman have emphasized the importance of incising the small fibromuscular bundles which move the bladder to the peritoneum near its apex. With these divided it is possible to push the bladder completely behind the symphysis, and the peritoneal flap thus obtained is very thin and flexible and would in no way interfere with development of the pregnant uterus. Following myomectomy it is possible that the raw uterine surfaces at the site of the hysterotomy incisions form solid adhesions with an insufficiently displaced bladder.

The authors conclude that in spite of these occasional obstetrical complications, vesical peritonization has too many advantages to be abandoned. It not only permits excellent end results in conservative surgery but a considerable number of pregnancies may be saved in patients operated on for myoma and adnexitis. An important factor in technique is the adequate retrodisplacement of the bladder.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

A Case of Anuria Due to Mercury Bichloride Poisoning Cured by the Intravenous Injection of Novocain
(Un cas d'anurie due à l'intoxication par le sublimé, guérie par des injections de novocaïne intraveineuse)
KAREL UHLIR. *J. urol. méd. Par.* 1948 54 48.

After a brief review of the pathology the author describes two clinical aspects of mercury bichloride poisoning: (1) the initial polyuria and albuminuria which results after a few hours in anuria (this concerns the mild cases in which diuresis is re-established and followed eventually by polyuria of several weeks' duration) and (2) the severe condition in which anuria occurs without preceding polyuria.

The general management consists of the administration of fluids, gastric lavage and the administration of an antidote if such exists.

The author had no opportunity to try BAL, British antilewisite.

In severe cases the medical treatment is without result. The same is true for decapsulation or nephrostomy performed in order to promote kidney function. Also splanchnic or lumbar sympathetic block with novocain has been without result, although efficient in other cases of anuria. The intravenous injection of novocain recommended by French authors has brought good results in anuria caused by bilateral kidney calculus, sulfanilamide or chronic nephritis.

The author describes the case of a 47 year old patient who in a suicidal attempt took 12 gm. of mercury bichloride. The routine medical treatment was without result and the patient was anuric with advancing azotemia for 5 days. The author injected from 10 to 15 c.c. of 1 per cent novocain solution twice a day intravenously from the fifth to the eighth day and 15 c.c. of this solution once a day from the ninth to the sixteenth day. The urinary output started 3 hours after the first injection with albuminuria and casts. After 24 hours it was 75 c.c. and it gradually increased within the following 6 days to 1600 c.c. per day at the end of the twelfth day after onset of the condition. From then on the range of output was between 1500 and 3500 c.c. per day. The blood chemistry became normal and at the end of 2 months the urine was free from albumin and normal kidney function was present.

ERNEST BORA, M.D.

A Contribution to the Production of Experimental Nephritic Lesions. Nephrosclerosis Produced by Cellophane (Contributo alla produzione di lesioni nefritiche sperimentali. La nefrosclerosi da cellophane) ROBERTO CACCI. *Arch. Ital. urol.* 1947 22 217.

In 18 dogs experimental nephritic lesions were produced by wrapping their kidneys in cellophane ac-

cording to Page's method. The transperitoneal approach was used and first one kidney and 20 days later the other was surrounded by cellophane. In this manner perirenal as well as parenchymal lesions were produced. Changes in the interstitial tissues, glomeruli, tubules and blood vessels were thus provoked. The relatively chronic changes greatly resembled those in human nephrosclerosis. The histologic changes were analogous to those in chronic interstitial nephritis. Angiographic examinations of the vascular network supplemented the histologic studies.

The author concludes from his investigations that the use of cellophane for wrapping the kidneys merits especial attention among the various methods of producing experimental nephritis, because the characteristic complex of such lesions may thus be provoked and because the relative chronicity of the evolution of the process allows the utilization of experimental animals for scientific studies. No other experimental method is capable of producing such intensive parenchymatous as well as perinephritic changes as those created with cellophane. JOSEPH K. NARAY, M.D.

Injury of the Ureter from Gunshot Wounds. CARL F. ROUSCH. *J. Urol. Balt.* 1948 60 65.

Because of inadequate facilities during World War I injury to the genitourinary tract was accompanied by a high mortality rate since few patients lived to reach a base hospital. However in World War II conservative surgery and early and adequate diversion of both the urinary and fecal streams proved to be the foremost factors leading to good results. Of equal importance was the administration of chemotherapy with the onset of injury and the rapid transporting of casualties to rear hospitals.

Because of the predominance of penetrating wounds which are the most likely to occur in war ureteral injury is frequently overlooked, especially in the stress of emergency work. Furthermore, injuries to important structures intimately related to the ureter are often so severe as to completely mask evidence of ureteral damage and often death occurs so rapidly that ureteral injury is not discovered.

The pelvic ureter is more frequently injured in gunshot wounds because it is not so well protected as the remaining portion and is more fixed than the latter which is small, elastic, and often associated with the extensive visceral injuries. Complete division of the ureter is more common than partial severance and early diagnosis is imperative to conserve renal tissue and obtain the best functional results.

In the greater number of cases pyelography is the only means of making a diagnosis. Urinary fistula is the characteristic symptom of unrecognized ureteral injury occasionally it is transitory the leak arising

from a partial rupture small enough to heal spontaneously and often followed by ureteral stricture.

Extravasation of urine arising from the ureter even without free drainage, is far less severe than that from the bladder or urethra. When the ureter has been severed and the tissues have obliterated the trace of the bullet, extravasation of urine forms a mass in the adjacent region with sepsis.

The first consideration in treatment is relief of shock. The manner of treating the ureteral injury depends on the location, extent of the injury and the time at which the lesion is discovered.

In partial rupture of the ureter, extraperitoneal drainage and insertion of an indwelling ureteral catheter with or without suture often are adequate. When complete division of the ureter exists, end-to-end anastomosis over a ureteral catheter with diversion of the urine, is the procedure of choice.

Occasionally, the ureter can be implanted into the bladder when the pelvic ureter is injured. There are very few cases in which ureterointestinal anastomosis is possible. When the condition is recognized early nephrectomy is the standard method of treatment for a fistula of the abdominal ureter. In late recognition of the presence of a urinary fistula and renal infection nephrectomy is the method of choice.

JOHN A. LOER, M.D.

Carcinoma of the Ureter. THOMAS GUALTIERI, JAMES J. HAYES, and ABRAHAM D. SEGAL. *J. Urol. Balt.*, 94:5, 59, 1935.

TWO CASES of primary carcinoma of the ureter are presented, one with early changes and the other long-standing with late changes including perforation and a perinephric abscess. In both cases, filling defects in the ureters were noted on pyeloureterograms and an efflux of bloody material was noted when the catheters entered the lower ureters. In the early case the return through the catheter became clear upon reaching the renal pelvis.

The similarity of the malignant lesions of the conduit system of the urinary tract is noted, and the pathogenesis is discussed.

We believe that future investigation of this problem must concern itself with the effects of the various methods of therapy at hand as also those yet to come that the goal must be prevention or halting this, a reversal of the abnormal process with the object of obtaining an absolute cure.

Perhaps the answer may be found in the hormones, enzymes, and their attendant biochemistry in x-rays and radium, in galvanism and iontophoresis, or even in the domain of the atom, when and if man finds his way around to controlled atom fission therapy.

JOHN A. LOER, M.D.

Indications and Immediate and Remote Results of Ureteroileostomy. (Indicazioni e risultati immediati e remoti della ureteroileostomia). GIORGIO NICOLINI. *Urologia*, 94:5, 151, 1935.

The following indications for the operation of ureteroileostomy are cited by the author. Inverted

ate obstinate tuberculous cystitis, extrophy of the bladder, carcinoma of the bladder and cancer of the prostatic gland with intensive cystitis.

The first method by Coffey is preferred by the author to other modifications of the operation.

As to the immediate results, all 5 patients with tuberculous cystitis recovered, one patient with grave cystitis resulting from a cancer of the prostatic gland also recovered, of 3 patients with an extrophy of the bladder one died and one recovered, and of 11 patients with a cancer of the bladder 8 recovered and 6 died.

One patient with extrophy of the bladder succumbed to paralytic ileus. Three patients with cancer of the bladder died from pyelonephritis, one from peritonitis, one from paralytic ileus, and one from pneumonia. The total immediate postoperative mortality in 23 cases was 33 per cent. Of the patients with benign lesions, 14 per cent and of those with malignant conditions of the bladder or the prostatic gland, 40 per cent died as the result of the operation.

A detailed analysis of the remote results convinced the author that ureteroileostomy represents the method of choice in the treatment of grave forms of tuberculous cystitis. In extrophy of the bladder compatible with life this procedure or the Maydl operation may be performed. Good palliation may be obtained in malignant lesions.

As to immediate postoperative fatalities, paralytic ileus develops in direct relationship to the duration of the operation, while peritonitis and pyelonephritis are consequences of the necrosis of the isolated ureteral segment.

All patients had perfect continence and were evacuating urine at regular intervals of several hours. The tolerance was better in women than men.

JOSEPH E. NARAT, M.D.

Experimental Contribution to the Implantation of the Ureters into the Rectum according to Bergenhem's Technique. (Contributo sperimentale all'impianto degli ureteri nel retto con la tecnica di Bergenhem). VINCENZO LAURICELLA. *Arch. Ital. med.*, 94:7, 245.

Unilateral or bilateral implantation of the ureters into the rectum according to Bergenhem's technique avoids numerous disadvantages accompanying other operative methods. A perfect anatomic union of the implanted ureters with the rectum can be observed after the operation. The resulting ureteroenterostoma possesses a valvular mechanism which prevents an enteroureteral reflux. The newly created stoma shows no tendency toward the formation of a stenosis. Furthermore, the application of the aforementioned method creates conditions more physiological than those following other operative procedures.

The following indications are enumerated by the author: extrophy of the bladder, selected cases of cancer of the bladder, tuberculous of the bladder with involvement of one kidney, tuberculous of the prostatic gland and seminal vesicles, incurable vesicovaginal fistula, cases in which great difficulties are

encountered in reimplantation for uterine cancer, and selected cases of painful contracted infected and ulcerated bladder.

The method consists of the formation of a rosette from the vesical mucosa around the severed end of the ureters and implantation of the ureters into but tonholes in the rectum.

The author's conclusions are based on the experiments on 5 dogs. In 3 a unilateral and in 2 a bilateral, implantation of ureters was performed.

BLADDER, URETHRA, AND PENIS

The Repercussion of Vesical Neck Dysectasia on the Urinary Tract Above the Lesion (Du retentissement des dysectasies cervicales sur les voies urinaires sus-jacentes). JEAN BAUCHART and JEAN GARNIÈRES. *J. urol. méd.*, Par. 1948, 54, 16.

The authors studied the effects of dysectasia of the vesical neck on the urinary tract. He divided the cases into three groups. First he considered lesions of the neck: (1) anatomical lesions with sclerosis and (2) functional contractions due to hypertonicity on a nervous basis. A differentiation between the functional and organic types is frequently impossible and eventually sclerosis will be present in both.

The second type of cases presented a hypertrophic prostate gland due to adenoma and the third type of cases presented prostatitis.

Trabeculation and cellulitis were found upon cystoscopy and cystorontgenography revealed irregular walls with holes and studded with raised areas. There was residual urine. Of greatest importance however were the disturbances of kidney function.

Among the many renal function tests the authors consider intravenous urography as the most conclusive.

When the patient presents a contracted bladder neck dysuria is rarely absent. A residue is usually present when the patient consults his physician. It is constant and progressive. Cystoscopy reveals cellulitis and trabeculation and the residue varies from 100 to 150 c.c. Kidney function is initially good. Sounding and irrigations might relieve the condition temporarily but eventually resection which brings cure is necessary.

The initial stage is short. The residue increases quickly to from 200 and 300 c.c. with consequent bladder infection, the formation of a diverticulum, vesicoureteral reflux, kidney damage, uremia and pyelonephritis.

An infected residual urine was present in 55 of 65 cases. A bladder diverticulum and a reflux were present in 25 of 65 cases. Approximately 38 per cent of the patients have a reflux, a diverticulum or both. The diverticulum is considered to be acquired and not congenital. Azotemia was present in approximately 30 per cent and is less frequent in patients with a diverticulum. It is concluded that the diverticulum functions like a safety valve. A parallel be-

tween the residue and azotemia could not be established. Intravenous urography has proved to be a superior method which detects kidney damage earlier than determination of the blood chemistry. In 16 cases the blood chemistry and the intravenous urogram concurred. In 5 cases the superiority of the intravenous urography over determination of the blood urea, Ambard's constant, and phenolsulfonphthalein value could be demonstrated.

The renal infection, pyelonephritis, is thought to be hematogenous. The kidney infection remains in conspicuous with vague lumbar pain, digestive discomfort, dryness of the tongue and polyuria. In rare cases, an acute pyelonephritis might develop.

When the patient has an adenoma of the prostate gland residual urine and dysuria are also present but their appearance is different. Cases of acute complete retention are frequent as compared with cases of contracted vesical neck. Among 280 patients, 149 revealed acute retention and 131 no retention. Characteristic of the acute retention in adenoma is its reversibility by simple catheterisation with complete loss of the residual urine. It is rarely caused by a middle lobe. Eleven of 14 patients with an enlarged middle lobe had no acute retention at any time.

Dysuria is less marked. It was absent in 78 patients, slight or temporary in 165, marked in 34 and unknown in 3. In comparing cases of acute retention with those without retention, dysuria was absent in 59 against 19, was slight or temporary in 86 against 79, was marked in 3 against 31 and was unknown in 1 against 2.

The residual urine in 23 per cent of 90 cases with out acute retention ranged from 0 to 100 c.c. In contradistinction in cases with acute retention it ranged from 0 to 100 c.c. in almost 77 per cent. The detrusor muscle is capable of regaining its strength in cases with acute retention once this has been relieved.

Two groups are differentiated: (1) cases with acute retention with slight or absent dysuria and a low residue of urine, and (2) cases without acute retention, with frequent dysuria and a marked degree of residual urine. The explanation is thought to be the invasion of the smooth internal sphincter by the adenoma in the second group. In the first group, the internal sphincter remains undamaged for a long period.

This determines the indication for intervention. In cases with a low residue of urine but persisting dysuria, intervention should be advised. A patient with no dysuria should be regularly supervised in order to intervene in time.

Bladder infection is frequent—less than one-fifth of the cases had a clear urine without infection. Some cases with a high residue remained uninfected. Bladder diverticulum and ureteral reflux are infrequent. Diverticula were observed in 8 of 280 cases of adenoma, whereas they were seen in 21 of 66 cases with contracted vesical neck.

Only 1 case of reflux was seen as compared with 9 in the group with contracted vesical neck. Renal

function is less impaired in cases of adenoma than in cases with contracted vesical neck.

In 33 per cent of the 131 cases without acute retention, blood chemistry revealed damage to kidney function. Among them was the case with reflux and all but 1 case of diverticulum. The diverticulum seems to play the same role as in cases of contracted vesical neck. Kidney damage in cases without acute retention is about the same as in the cases of contracted vesical neck. The cause is again thought to be the involvement of the internal smooth sphincter. A relationship between the blood chemistry and residual urine revealed that the blood chemistry remains normal with a residue below 100 c.c., and that only in one-half of the cases with a residue above 300 c.c. the blood chemistry is elevated.

Among 140 cases with acute retention 24 per cent revealed damaged renal function upon determination of the blood chemistry. This was almost 10 per cent less than of those in which there was no retention. Only 6 patients had a severely damaged kidney function as demonstrated by blood chemistry determinations (4%). The renal damage was frequently slight and temporary with a rapid return of the blood chemistry to normal. This was demonstrated with the urea Ambard's constant, and phenolsulfonphthalein tests during acute retention and after the retention had ceased. Renal damage appeared later, was less important, and was frequently reversible. This was contrary to the findings in cases of contracted vesical neck. The lack of invasion of the smooth internal sphincter was the cause of the clinical picture. Repeated acute retention was of no greater consequence for the kidney function than a single instance of acute retention. A comparison of the blood chemistry determination with the intravenous urogram revealed that in cases presenting no acute retention the findings were parallel in 23 cases. The superiority of the intravenous urogram over the blood chemistry determination of blood urea, phenolsulfonphthalein, and Ambard's constant was demonstrated in 5 cases. In cases of acute retention the results of the blood chemistry determinations and of intravenous urography were parallel in 19 cases and in 3 cases the urogram gave better information than the blood chemistry determinations.

The phenolsulfonphthalein test and Ambard's constant test were more sensitive than the blood urea test.

The authors conclude that in a number of cases (the very good and the very poor) the laboratory findings and the intravenous urograms are of equal value. In borderline cases the blood chemistry tests give inadequate information. The Ambard's constant and the phenolsulfonphthalein tests give more information, but the intravenous urogram is superior to all. This is important for the indication for intervention.

In the cases of prostatitis the following forms are distinguished: a sclerosing form and a hypertrophic diverticular form. Occasionally the latter is superimposed on an adenoma presenting an adenomitis.

Forty cases were studied. Thirty-two cases were examined by cystoscopy and 15 sclerotic and 17 hy pertrophic cases were found.

Acute retention might occur during an acute flare-up and was observed in 5 cases (1 sclerotic form, 3 hypertrophic forms, and 1 adenomitis). Diverticula are not rare, being found 6 times among 40 cases. Diverticula are rarer than in cases of contracted vesical neck but more frequent than in cases of prostatic hypertrophy. No ureteral reflux was seen. Blood chemistry determinations revealed kidney damage in 35 per cent of the cases. The intravenous urogram disclosed kidney damage in cases in which the blood chemistry determinations did not indicate it.

Prostatitis with ureteral encroachment might rapidly lead to kidney damage. The repercussions caused by prostatitis are in between those caused by the adenoma and the contracted vesical neck.

Cancer of the prostate, especially the scirrhous, develops like a contracted vesical neck. The slow growth might delay the impairment of the renal function. A proliferating epithelioma causes even less dysectasia than a scirrhous.

Cancer of the prostate is not always characterized by cervical dysectasia. It might develop silently without urinary symptoms and become manifested by metastases.

Summary. In a contracted vesical neck, dysuria is the main symptom. It remains constant and the detrusor muscle develops diverticula in its fight against the obstacle.

Adenoma without acute retention, found in somewhat less than 50 per cent of the cases, imitates the picture of a contracted vesical neck. It is less progressive and ends with distention and later kidney damage. In cases of adenoma with acute urinary retention the residual urine remains low and kidney damage is delayed because invasion of the internal sphincter does not occur. Temporary kidney damage during acute retention is reversible. The repercussion from prostatitis occupies a place between that of the two aforementioned conditions.

EARLST BORG, M.D.

GENITAL ORGANS

Hydronephrosis in Prostatic Obstruction. HENRI L. KARPENBERG and FAY H. SQUIRE. *J. Urol.*, Balt., 1943, 60.

The routine use of intravenous urography in prostatic obstruction has become an established procedure on the authors' service at the Presbyterian Hospital, in Chicago. A review of 408 intravenous urograms made during the period from 1933 to 1937 and from 1945 to 1947 was undertaken and the cases were divided into two groups designated as A and "B".

In group A the average duration of symptoms before medical aid was sought was 60.5 months and in group B 43 months, a differential of nearly 1 1/2 years. In group A there were 80 cases of hydrone-

phrosis an incidence of 44.44 per cent in group B there were 75 cases in which hydronephrotic changes were observed an incidence of 33.43 per cent.

For purposes of designating the degree of hydronephrosis the cases were graded on a basis of 1 plus to 3 plus. The evidence indicated little difference in degree of hydronephrosis in the two groups. Of the patients with carcinoma of the prostate 66.66 per cent of those in group A and 41.66 per cent of those in group B had hydronephrosis.

The authors conclude that hydronephrosis occurs more frequently in patients with malignant obstruction than in those with benign obstruction, and that it is in direct relationship with the duration of the disease in both cases. JOSEPH E. MAURER, M.D.

Primary Carcinoma of the Seminal Vesicle. E. M. GAZ. *Brit J Urol* 1948, 20: 72

The author records 2 cases of this rarely diagnosed tumor from the Toronto General Hospital, Toronto, Canada during a period of 40 years. A review of the literature shows only 31 previously recorded cases of primary carcinoma of the seminal vesicle. The case of Labbe in 1883 is generally accepted as being the first case described.

In many cases the diagnosis was not made during life. In others the diagnosis was suspected only when the clinical picture was well advanced with retention of urine, hematuria, dysuria and loss of weight as prominent symptoms. Cystoscopy usually showed signs suggestive of obstruction and secondary tumor invasion. Rectal examination has frequently disclosed a hard nodular or irregular fixed mass above or in the region of the prostate. At autopsy metastases were widespread chiefly to the lungs, liver, lymph glands and mesentery.

In Case 1 the patient was a totally asymptomatic 65 year old man who in 1932 during the course of

a routine health examination was found to have a hardening over the right lobe of the prostate. Various examiners over a 2 year period entertained the diagnosis of carcinoma of the prostate and seminal vesicle or prostatic calculi the latter being the favored impression. In 1934 the patient developed hematuria and back pain. Roentgen examination revealed destructive vertebral and rib lesions. The patient died within a few months following the sequence of cystitis, pyelonephritis and uremia. At autopsy primary carcinoma of the seminal vesicles was found histologically forming columns of small vesicular cells. There was no invasion of the prostate but the tumor growth involved the bladder wall about the ureters.

Case 2 was that of a 36 year old patient who in December 1946 complained of lower abdominal pain radiating to the external genitalia. Treatment for seminal vesiculitis was unavailing and the patient had a weight loss of 25 pounds in a few months. In April 1947 a firm nodular mass 3 inches in length above the prostate on the left was considered tuberculous. There was a rapid downhill course following laparotomy in June 1947 at which time there was considerable fluid in the abdomen and biopsy sections of the hard mass above the prostate revealed a highly anaplastic tumor consisting of large polyhedral hyperchromatic cells. The patient died before an autopsy was not performed.

In the second case the tumor was obviously inoperable when first seen. The report of the first case however is instructive in emphasizing a well established urological dictum. Even in the absence of symptoms when a small suspicious mass in the prostate or vesicle is found consideration should be given to exposure through the perineum and if frozen section, with a view to radical treatment if it is cancerous.

ALLAN E. SWERDLOFF, J.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Evolution and Causes of Juengling's Disease (Evoluzione ed eziologia della malattia di Juengling) G. GREENGLINTZ. *Chir. org. superio.* 1943, 32, 50.

The author presents a supplementary report of a case of Juengling's disease reported by him 7 years previously. The symptoms occurring in this condition are known as the Besnier Boeck-Schaumann syndrome (benign lymphogranulomatosis, benign diffuse reticuloendotheliosis) which in the skeletal system forms the disease of Juengling (cystoid osteitis tuberculoidea multiplex).

Comparative films taken in 1940 and 1947 are shown of the shoulder girdle and the feet. There has been definite improvement of the cystic areas in the intervening 7 years.

The patient whose case is reported was employed as a housemaid and presented herself after an interval of 7 years because of increased osteoarthritic manifestations of the shoulders and hips.

The author explains that the condition is seen only rarely in Italy. In conclusion he stresses the following points.

The clinical condition is a definite entity in the skeletal system.

In spite of the fact that the condition is considered benign as far as healing of the cystic areas is concerned, the associated osteoarthritic condition is progressive. CARLO SCUDERI, M.D.

Muscular Torticollis. FREMONT A. CHANDLER. *J. Bone Surg.* 1943, 30-A, 566.

This article is based upon a study of 225 patients with muscular torticollis (101 of these cases had been previously reported).

The accepted theories and the literature on this subject are quoted and it appears that most writers have agreed that the tumors of the sternomastoid muscle are hematomas caused by tearing of the muscle during birth, often in breech presentations. The author believes that malposition in utero with possible pressure and ischemia of the sternomastoid may render the muscle atrophic, maldeveloped, fibrous and shortened and therefore liable to damage during delivery.

The treatment advised in older children is detachment of the sternal and clavicular heads of the sternomastoid muscle, followed by retention in an overcorrected position. In the infants (43 infants under 1 year are included in this series) even when only a few weeks old the author believes excision of the fibrous tumor followed by the application of a light plaster splint to maintain the overcorrection for 3 to 4 weeks is justified. The operation is not difficult, but the spinal accessory nerve must be protected and disengaged from the tumor.

Microscopic section of the tumor which is white and fibrocartilaginous, shows abundant fibrous replacement of degenerating muscle fibers, and no evidence of hematoma at all, even in very young infants. There was no blood clot or residual blood pigment observed. NEWTON C. ALLEN, M.D.

Coxa Plana. M. BECKETT HOWARTH. *J. Bone Surg.* 1943, 30-A, 601.

The author reports on 115 cases of coxa plana seen at the New York Orthopaedic Hospital between 1935 and 1944.

Coxa plana is a self-limited disease of the hip, of unknown etiology usually occurring between the ages of 4 and 10 years. The name is not altogether satisfactory but is the best so far suggested. The author believes that the term "aseptic necrosis" is not accurate and should be discarded. It is one of a group of diseases the osteochondroses, which include slipping of the upper femoral epiphysis, coxa magna, Osgood-Schlatter's disease, apophysitis of the calcaneus, and Koehler's, Freiberg's, Kleinbock's and Scheuermann's diseases. They are all characterized by degenerative changes due to circulatory disturbance, but occur at various ages and in various epiphyses or small bones.

Eighty-five per cent of the cases encountered occurred in boys, and 90 per cent were unilateral. Either hip may be affected. The physical type of the child appears to have no relation to the disease, and an occasional patient presented a definite endocrine disturbance. Coxa plana may occur during the course of treatment of congenital dislocation of the hip in about 25 per cent of the hips, as a result of immobilization in a position of tension, particularly extension, abduction, and internal rotation. This position "wings out" the blood vessels and interferes with the circulation resulting in degenerative changes.

Pathologically there is swelling, edema, and hyperemia of the soft tissues, capsule, perosteum, and, especially of the synovial membrane. Microscopically there is edema, hypervascularity and thickening of the synovial membrane often with villous formation. Perivascular lymphocytic and plasma cell infiltration is usual.

The disease may be divided into four stages: (1) the early or incipient stage, in which there are only soft tissue changes and mild symptoms and signs associated with synovitis; (2) the degenerative or active stage, lasting 1 or 2 years, in which degeneration in the head and softening at the epiphyseal disc occur; (3) the healing stage, lasting 3 or 4 years, in which the dense areas are replaced by granulation tissue and finally by normal bone; and (4) the residual stage, in which only the deformity with its consequent symptoms remains. In each stage the soft tissue changes precede the bone changes.

In the early stage, the most common symptom is a slight limp, which increases with the intensity of the disease. Pain is rarely severe enough to prevent walking often it is only a mild ache or stiffness. It is relieved by rest, aggravated by activity or injury and referred to the groin, medial aspect of the thigh, or knee, following the distribution of the obturator nerve. The acute symptoms gradually subside and are replaced by symptoms due to faulty mechanics associated with the deformity. Eventually the symptoms of osteoarthritis may supervene. The earliest and most important signs are limp, limitation of motion, and pain at the extremes of motion, especially lateral motion and rotation. In time slight atrophy of the thigh and slight shortening of the femur occur because of the flattening of the head and shortening of the neck.

Laboratory tests are of only incidental value in this disease. The first evidence of the disease in the roentgenograms is a globular swelling of the capsule. The joint space appears wider medially because of a slight lateral subluxation. It appears wider superiorly because of a flattening of the ossified portion of the epiphysis. Soon after the onset, the epiphyseal line appears wider and is irregularly decalcified at its junction with the neck. An irregular dense area soon appears in the capital epiphysis usually in the central portion. Gradually the dense area becomes irregularly decalcified, but it may enlarge at the same time. During the decalcification, the head becomes wider flatter and thinner and the neck becomes thicker and shorter. Gradually the soft tissue swelling subsides the epiphyseal line recalcifies, while the proximal surface of the neck becomes convex and grows into the head. More gradually, the decalcified areas are recalcified. Eventually normal trabeculation occurs, but the head maintains its mushroom shape and tends to remain subluxated.

In untreated cases, coxa plana follows a characteristic course over a period of from 4 to 7 years and always heals but with some residual deformity.

The primary treatment for the disease at the present time is rest. Rest in bed is the surest and simplest way of securing rest for the hip but it must be continued for 2 or 3 years from the onset in the average case. It was used alone in 30 cases of this group. It is especially important in the incipient stage when the symptoms and signs are acute, and, later when there is a great deal of decalcification of the head. Traction for 2 or 3 weeks is desirable for the relief of pain and spasm but it should not be prolonged. Rest should be continued until there is no pain or spasm with motion and until the roentgenograms show sufficient regeneration of the head for safe weight bearing.

The best ambulatory treatment is obtained by the use of a sling and crutches this method was used in about 20 cases of this series. A webbing belt with a shoulder strap, similar to the Sam Browne belt, is used for the sling which is suspended from the belt and encircles the ankle. The lower extremity is thus

suspended with the hip and knee in flexion. The nonweight bearing long leg brace with a built up shoe for the good side may be used but it is heavy and clumsy more expensive, and less satisfactory. Crutches alone may be used, but generally the child cannot be depended upon to keep his weight off the extremity. Immobilization in a plaster cast or traction brace tends to increase the limitation of motion, especially if continued for weeks or months, but it may be used for 2 or 3 weeks for the relief of acute pain and spasm.

The drilling operation was used in about 50 cases from 1928 to 1939 for hastening the healing of the disease process. The follow up period extended from 8 to 18 years. The operation has been found most useful when performed in the progressive stage or in the early stage of repair. The total amount of degeneration and the residual deformity appeared to be reduced by this procedure and the period of convalescence has been shortened by about one third. No new degenerative areas appeared and repair began promptly after the operation. In order to be most effective the operation must be combined with a period of several months of nonweight bearing. Better results were obtained in the group of patients operated upon than in the other group.

Histologic Studies on Arthritis Deformans of the Hip Joint. Alterations in the Osseous and Cartilaginous Fibrillary Framework. Studies in Polarized Light (Ricerche Istologiche nell'artrosi deformante dell'anca. Le alterazioni della trama fibrillare cartilaginea ed ossea. Ricerche in luce polarizzata) PAOLO LUGIATO *Chir. org. movim.* 1948 32 301

On the basis of the material procured in doing arthrodeses of the hip joints in 15 patients with arthritis deformans at the University of Milan, the author discusses the results. Microscopic sections of from 16 to 20 microns in thickness were studied with Nicol prisms as the source of the polarized light. The microscope used was the Koristka. Euskop with an achromatic objective 22x-5x-45x and a Huyghens ocular 6x and 8x. The polarizing apparatus was the homocentric condenser produced by Koristka. In addition to the simple exposures with the crossed Nicol prisms every specimen was also examined by the chromatic method by inserting between the two prisms a compensator provided by Koristka which consisted of a slab of mica of the proper thickness. The procedure is the same as that used by mineralogists in the study of rock crystals.

It is shown that by this method not only the shape and course of the fibers composing the lamellae of the cartilage and of the bone—for the manner of doubly refracting the polarized light by the fibrils in the cartilage differ entirely from that of the osseous elements—can be demonstrated, but also that changes in their arrangement and composition can be detected before anything abnormal can be seen with the ordinary staining methods of study. It

can be shown how the interlacing fibrils of the surface layer of transversely directed elements first become altered in their capacity of transmitting the polarized light waves and finally lose the power of response and disappear. Next the middle layer of arcuate fibrils are affected and finally the deeper layer of radial fibrils. The subchondral osseous elements then invade the deeper portions of the cartilaginous elements, and finally become eburnated and substitute for the undermined and destroyed cartilage. The behavior of the polarized light in some of these stages is not explainable by our present knowledge of optics and is merely cited by the author as a suggestion for future research in this field.

The findings by this method were finally checked by ordinary dark field illumination methods, and these findings were deemed sufficiently accurate to dispense with the ordinary staining methods.

The author hopes to use this method, not only for the study of arthritis deformans of the hip joint, but of other joint troubles as well.

JOHN W. BRENNAN, M.D.

General Concepts on Traumatic Parameniscitis of the Knee (Parameniscitis traumática de la rodilla, conceptos generales) HECTOR DAL LAGO. *Rev chirúrgica*, B Air 945, 7-44.

The parameniscus is the space about the meniscus containing blood vessels and nerves. It is believed to be the only part involved in any inflammatory process. Parameniscitis occurs as the result of trauma to the meniscus with or without rupture, or trauma directly to the parameniscus without involvement of the meniscus. Strain or compression of the semilunar cartilage with or without fracture may cause injury to the pericardial structures and produce edema, vascular and tissue proliferation, pain and swelling. It is contended that these constitute the ruptured meniscus syndrome. The same sequence however may occur without damage to the semilunar cartilages.

Parameniscitis may be acute or chronic, and treatment is rendered accordingly. The condition may regress spontaneously or persist through the chronic stage to cystic degeneration and necessitate resection of the meniscus.

STEPHEN A. ZIEGLER, M.D.

Radiological and Histological Studies on the Aspecific Osteolysis which is Associated with Vascular Disturbances, with Exceptional Report of a Familial Case of Total Loss of Bone of One Toe of a Foot with Symmetrical Atrophy of All the Other Toes (Contributo radiologico ed istologico alle osteolisi aspecifiche accompagnanti turbe vasomotorie eccezionale reperto a sfondo familiare di totale scomparsa dello scheletro di un dito del piede con atrofia ossea simmetrica di tutti le altre dita) GIUSEPPE T. MOTO. *Chir. org. merim.* 945, 33-52.

The author describes in detail the case of a woman who presented since the age of 15 a vasomotor syndrome of all of the toes of the feet. Roentgenographically it was possible to demonstrate a marked atrophy of all the phalanges and total absorption of

all the bones of one toe. Such changes must have had a familial background, because a sister of the patient presented a very similar clinical picture. The author does not enter into a discussion of the differential diagnosis; however, he believes that the syndrome simulates Raynaud's disease.

The author describes in detail the histological changes observed in the patient and the gradual change of the bone to connective tissue, also the complete absence of any regenerative action of bone. This gradual change of bone to fibrous tissue is the usual change observed in neurotrophic bone lesions. However, this was an unknown clinical picture because there was no resulting gangrene which is the usual complication in this type of case.

The patient was a woman of 32 years of age with only abnormal background was pulmonary tuberculosis which had been treated for 5 years by pneumothorax. She gave a history of having always complained of cold hands and feet. Detailed laboratory findings are given and the history and photograph of the sister's foot.

The author gives a review of the bibliography and differential diagnosis. Histological studies were made of a biopsy specimen corresponding to the bony part of the fourth toe of the left foot. Microscopic sections showed a fibrotic tissue in various stages of regeneration. The blood vessels showed a cellular hyperplasia of the intima. There was no evidence of thrombosis, necrosis, or exudative phenomena.

CARLO SCUDER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Cup Arthroplasty of the Hip. WILLIAM H. BAKER and FRANK S. BARR. *J. Bone Surg.* 1945, 30-A:67.

Detailed analysis of cases of cup arthroplasty of the hip revealed that patients should be selected carefully for this operative procedure on the basis of (1) physiologic age, (2) temperament and ability to cooperate, (3) reconstructive possibilities of the hip, as analyzed from roentgenograms, (4) muscle power, and (5) occupation.

All patients should be acquainted with the possibilities of failure and success, and the alternate operations should be discussed with them. In case of disease of both hips, or in cases in which degeneration of the opposite hip is expected, there is no alternative. Drilling operations, cheilectomy, facial arthroplasty and other methods have not stood the test of time. Osteotomy to change the weight-bearing surfaces of an already incongruous and worn-out joint does not seem reasonable. Neurectomy of the obturator nerve may help. It has not proved of great help in relieving persistent pain following cup arthroplasty; however the number of cases in which it has been done by the authors is not great.

Prostigmine has been used after operation in some cases to relieve muscle spasm and pain. The results were not very encouraging, although several patients believed that it helped considerably. Cures has

been used in conjunction with physical therapy in a few cases to obtain muscle relaxation with equivocal results thus far.

Some of the best results obtained have been in cases in which the degenerative process or mechanical irregularity of the head of the femur was in the formative stage and the acetabulum was involved only mildly. It is difficult to advise early operation for a patient who has distortion of the hip joint without much pain although one knows that ultimately the hip will break down. Perhaps in these cases, cup arthroplasties should be done before secondary osteoarthritis develops.

Comparison of the results recorded prior to January 1943 in the 88 cases in which cup arthroplasty was carried out at the Mayo Clinic with the results recorded in these same cases in this report, reveals a slight trend toward improvement. In 19 cases in which unilateral cup arthroplasty had been performed prior to 1943, improvement had occurred in the past 3 years as follows:

In 6 cases results which were poor at the time of the first study had become fair in 6 cases fair results had changed to good and in 1 case fair results had become excellent. In 6 cases results which were good earlier had become very good. In 10 cases the results had become worse. In 5 of these cases lucite cups had been used. The lucite cups in 3 of these cases are known to have fractured. 1 patient had a late abscess. No reason could be found for the downhill course of the remaining 6 patients. Results in 4 cases changed from fair to poor. In 3 from good to poor (lucite cups). In 2 from good to fair and in 1 case from very good to good.

It is the authors' impression that, as the patients gain confidence and muscle strength, the motion in their hips generally becomes better and the pain becomes less. A table is included to illustrate the over-all trend in all cases in which follow-up information was available.

Those opposed to cup arthroplasty will focus their attention on the percentage of poor results. It must be remembered however that the patients were severely disabled before operation and that the percentage of salvaged individuals far outweighs the percentage of those who have been made no better.

From this study it seems safe to conclude that vitallium-cup arthroplasty of the hip is a procedure which offers relief from pain, increased motion, and correction of deformity to a great number of patients. The results cannot be positively predicted, but better selection of patients and improvement in surgical technique should increase the percentage of good results from this surgical procedure.

Osteomyelitis of the Fibula (Le osteomyélite del perone) V. ACCARDI, *Chir. org. modim.* 1948 38 133

Twenty three cases of osteomyelitis of the fibula were observed during the period from 1941 to 1946 at the Orthopedic Center of V. Putti at Bologna, Italy. In 17 patients, more or less extensive resections of the fibular diaphysis were done. In the re-

maining 6 patients conservative measures (immobilization) were employed. The latter patients were not subjected to resection because there was not much disruption of the bone and no evidence of a tendency of the infective process to spread throughout the entire diaphysis.

The periosteum was always removed with the bone in the resections. This was done routinely because all of the patients were adults and the regeneration of new bone was not a factor and because it was feared that the periosteum if retained might result in the production of an osteomyelitic process in the newly formed bone itself. Care was exercised to carry the resection far enough into healthy bone tissue so that there was no danger of leaving infected bone in the stumps. As much of the lateral malleolus as possible was left intact—at least a few centimeters of the lower end of the fibula—in order to avoid the danger of infection of the tibiotarsal joint, and the development of an eversion deviation of the foot.

The results of treatment in every instance were excellent. Cure was attained in the course of 2 or 3 months. Only in 1 case was cicatrization delayed for 8 months. In 1 patient the wound had to be reopened 9 months later to remove a small sequestrum at the upper end of the distal stump. In a third individual a tubular transplant of skin was made to help close the extensive open wound.

On the basis of his experiences with this material the author feels justified in proposing that in the cases of comminuted fracture resulting from gun shot wounds with extensive lesions of the soft parts the diaphysis of the fibula should be resected at once.

JOHN W. BERNHARD, M.D.

Open Reduction of Pes Varus in Young Infants (La réduction sanglante du pied bot chez le jeune enfant) JACQUES LÉVY and PIERRE BÉRENGER, *Rev. chir.*, Par., 1948, 34, 97

A closed reduction of pes varus may be unsuccessful because (1) certain forms especially those associated with other malformations are irreducible (2) the treatment is instituted too late or (3) the correction is insufficient or is not maintained.

True recurrences are rare the great majority of recurrences being due to incomplete reduction combined with an insufficient osteogenesis.

If the conservative treatment fails or the condition recurs tenotomy of the Achilles tendon and an application of a plaster of Paris cast are usually done. The procedure frequently produces an incomplete correction and weakens the triceps muscle. Furthermore persistent adhesions not infrequently form. A prolonged immobilization may be followed by muscular atrophy and articular stiffness. Moreover a first reduction may produce grave osteogenic deformities such as flattening of the astragalus or convexity of the sole. Such deformities are favored by decalcification of the bones caused by immobilization of the involved extremity in a cast prior to the renewed reduction. Therefore the authors condemn repeated efforts at reduction and recommend in their

place an operative intervention directed chiefly toward the ligaments and tendons.

Two types of conservative open reduction are employed by the authors: (1) a limited operation, reserved for an isolated residual pes equinus usually observed within the first 3 years of life, and (2) extensive operations in cases with complicated malformations such as pes varus, pes equinus, metatarsus varus, which are usually found after the first 3 years of life.

The first type of operation consists of an elongation of the Achilles tendon, posterior capsulotomy and transcalcaneal traction. The more extensive operations may be subdivided into two groups: operations on the anterior and operations on the posterior parts of the foot. In the last type the Achilles tendon is elongated, the internal malleolus is severed in an oblique direction from above downward and from the inner toward the outer side, and the posterior tibial and flexor tendons are elongated according to the needs.

Slight deformities of the anterior portion of the foot may be treated in the same manner while more pronounced deformities require a supplemental second stage operation consisting of section of the internal plantar muscles. The posterior tibial tendon must remain untouched but the plantar aponeurosis may require sectioning.

The affected extremity remains in the cast for 3 months.

Sometimes the operations must be supplemented by cuneiform external osteotomy of the anterior apophysis of the os calcis or the cuboid. In children older than 4 years a transplantation of the anterior tibial tendon to the lateral border of the foot may be required.

Of 76 children, 13 could not be followed up, while 30 were operated on recently. Of the remaining 41, 16 underwent a bilateral operation. Good results were obtained in 33 patients, 13 of whom were operated on on both sides. JOSEPH K. NARAY, M.D.

The Indications and Technique of Surgery of Bone Tumors (Indikation und Technik der Knochen-geschwulstoperation) HANS HELLMER. *Chirurg*, 94:8, 19: 97.

This article is a brief survey of the most important methods employed in the surgery of bone tumors.

Biopsy is necessary in all doubtful cases. It should not be done with the curet but rather with a bone knife or chisel because curettage does not produce good specimens for histologic examination.

Curettage is in most cases sufficient for the treatment of cysts, giant cell tumors, and chondromas. If a large cavity remains after removal, the defect should be filled with bone grafts.

Removal with the chisel is practicable only in exostoses, osteochondroma, and osteoma of the cortex. The periosteum should be removed with the tumor to prevent recurrences.

Resection of the bone together with the tumor is the operation of choice for all benign tumors. If only

a part of the bone circumference is involved in the tumor, partial resection is sufficient. Total resection in long bones always calls for subsequent bone transplantation to restore the continuity.

The methods of plastic bone operations are:

1. The graft is taken by shifting a piece of bone from the contiguous portion of the same bone. This is possible only in partial resection of long bones. The solidity of the bone is always jeopardized by this procedure.

2. The graft is taken from the tibia, fibula, iliac crest, or rib. The chisel should be used rather than the saw because the heat produced by sawing damages the bone tissue. Either bone chips or a single large piece of bone may be used. In cases in which a large portion of the shaft of a long bone has to be resected, a Kuntscher nail or a Kirschner wire can be used to support the transplanted bone. No foreign body reactions were observed following this procedure. Bones which do not have to bear weight should be resected radically when affected by an osseous tumor. The author removed the entire occipital bone in a giant cell tumor, the suprascapular part of the scapula, the iliac wing, and the arches and transverse processes of vertebrae.

Primary malignant bone tumors should always be treated by amputation. Resection, even in early cases and small tumors, leads almost inevitably to fatal recurrences and metastases.

Bone metastases of malignancies in other organs are very frequent. In persons over 40 years of age, these secondary malignancies are the most frequent of all bone tumors. Usually they are inaccessible to surgery; however, there are three exceptions to this rule: single metastasis of a struma, single metastasis of a Grawitz tumor provided the primary tumor had been extirpated years ago, and the pathologic fracture of the femoral neck due to cancer metastasis. The first 2 can be treated by radical surgery as for primary tumors with a good prospect of success. In the case of the pathologic fracture of the femoral neck, operation will not save the patient, but internal fixation with a nail is indicated to relieve his pain and to get him out of bed.

Unbearable pains in vertebral metastases or in inoperable primary tumors with pressure on nerve plexuses are treated very successfully by chordotomy. WERNER M. SOLMITS, M.D.

FRACTURES AND DISLOCATIONS

Recent Advances in the Field of Medullary Nailing.
GERHARD B. G. KUNTSCHER. *Ann. chir. gyn. fasc.* 94:8, 37: 5.

Eight years have passed since medullary nailing was first done. The recent war has provided excellent opportunities to judge how far the procedure has come up to expectations and on what lines it has developed. Originally the method was inaugurated for the treatment of fresh fractures.

Medullary nailing ensures early movement and good fixation, abolishing the drawbacks and dangers

of immobilization. Postoperative treatment is not needed at all and hospitalization is therefore greatly shortened. The follow-up in 22 cases of fracture of the lower leg showed that there was no limitation of motion in the neighboring joints and in only 1 case was there noticeable waste of muscles. Except in 2 cases no edema of the lower leg nor disturbances in blood circulation could be noted. In 18 fractures of the humerus hospitalization averaged 11 days. All of the patients showed osseous union. The period of recovery was similar in 16 patients with fractures of the forearm. Many of these patients were able to do light work 7 days after the operation.

The only danger in medullary nailing is the danger of shock. A safe principle to follow is that no medullary nailing operation should last longer than an hour. The risk of infection is not very great because the fracture itself is not exposed and it is not in contact with the hematoma of the fracture. The nail is introduced through stab incision far from the site of fracture. There is a risk of infection at the point at which the nail is driven in but this infection does not progress along the nail if the threads are removed, i.e. it does not lead to infection of the fracture. Should an infection set in it would be a mistake to pull out the nail. The great advantage of medullary nailing is that it prevents even the slightest shaking motion of the fracture and this complete absence of motion is absolutely necessary for the healing of the infection. The fracture and site of introduction of the nail have to be opened the pus flowing out through the introduction hole and the nail itself acting as a drain. Bone infection in medullary nailing is absolutely typical. It does not lead to osteomyelitis but to local osteitis which also may lead to a characteristic sequestrum. This sequestrum does not affect healing because callus always grows around it. After the extraction of the nail, the sequestrum is easily removed. As the results presented in this article were obtained without penicillin there is reason to expect that the results will be a great deal better in the future.

The presence of abscesses, furuncles and previous wounds is an absolute contraindication for medullary nailing of a simple fracture.

Fractures of the distal third of the tibia can be firmly united only by means of a spreading nail on account of the conical widening of the distal third of the bone. The spreading nail has also been approved for treatment of fractures of the neck of the humerus. The nail is introduced a little above the olecranon and fills the cavity along the whole length of the shaft.

For the treatment of pertrochanteric fractures Y-shaped double nails have been used with success. This type of nail can be introduced via two stab incisions. Ambulation is possible after a fortnight.

Nailing of a simple fracture is done under fluoroscopic control. After the hematoma and edema have been massaged away the bone can be well felt under the skin. By taking it between two fingers reduction is done exactly. After this, Kirschner wires, with the

end ground off are introduced into the medullary space. When the wires leave the marrow space at the fracture a slight resistance of the muscles can be felt. The nails are driven in along the wires after which the wires are extracted.

Medullary nailing is of great value in other fields of bone surgery especially in osteotomy. It is not a mere substitute for the customary methods. It also helps to protect the periosteum and this is essential for nourishing the bone. Medullary nailing has also been accepted in the shortening of limbs, which by this method can be done exactly and with no appreciable risk. The writer recommends his counter incision saw for cases of this kind.

The author lists other conditions successfully treated by this method and concludes by stating that it should be attempted only after a study of the method at a hospital with a long experience in medullary nailing.

RUDOLPH S. REICH, M.D.

Additional Data Observed in Kuentscher Intra medullary Nailing at the Surgical Clinics of the University of Kiel (Weitere Erfahrungen mit der Marknagelung nach Kuentscher an der Chirurgischen Universitätsklinik Kiel) HEINZ GRIESMANN AND WILHELM SCHUTTMAYER. *Chirurg* 1947 17 18 316

This article is based on 155 cases of intramedullary nailing observed between January 1, 1944 and January 5, 1946. Fractures of 49 thigh bones, 64 lower leg bones, 14 humeri and 28 tibiae were treated by intramedullary nailing. This procedure was used in children only when conservative well established methods failed.

There were 46 simple fractures of the lower leg bones of which two-thirds were in the lower third of the tibia, less than one third were in the midportion of the bone and 4 were double fractures. It was necessary to use a different type of nail (Doppel Nagel) in the treatment of the oblique fractures. The so-called Spreiznagel gave very satisfactory immobilization and only occasionally a plaster cast had to be used for a short period. It was necessary that the nail maintained rigid fixation to counteract the push and pull forces and that callus formation was not impaired.

The operation was carried out by the technique described by Boehler. A small incision was made over the tibial tuberosity. By placing the part into the Boehler apparatus reduction was accomplished with only a little external help and the operation required as a rule from 10 to 15 minutes. In cases in which the marrow cavity was narrower than the nail (especially in the midportion of the bone) the intramedullary nail was reinserted through the medial malleolus.

In simple fractures ambulation of the patient was determined by his general condition. As a rule, patients were allowed to get up after the wound had healed. In the absence of any hematoma and any additional injury the patient was allowed to get up after the fifth day. Weight bearing was allowed after

the twenty-fourth postoperative day and the average patient was able to return to work within 3 months. The nail was removed only after visualization of firm callus formation on x ray examinations and under no circumstances was the nail extracted sooner than 3 months. In 3 cases there was delayed union of the fracture and resection of the fibula was necessary. This procedure was contemplated only after 8 to 12 weeks of delayed union. After resection of the fibula a plaster cast was used.

Intramedullary nailing was done in 15 compound fractures and in 7 cases the fracture united without any complications. Osteomyelitis was not observed.

There were 4 types of callus formation seen in routine x ray examinations (1) "cloudy" callus, (2) scanty callus formation with early and solid union, (3) callus formation predominantly on one side and (4) extensive reaction of the periosteum. The cloudy type of callus formation occurred quite early in the healing of fractures and in the presence of small fragments at the fracture site but only in fractures of the femur. The second type of callus formation was usually seen in fractures treated by nailing and in cases of ideal reduction. The callus formation on one side was seen in cases in which there was rotation of the bone fragments. Callus formation apparently was guided by laws of mechanics, i.e., pressure forces increase callus formation, distraction inhibits callus formation. In cases of angulation at the fracture site, callus forms on the concave side of the fracture. Increased periosteal reaction was usually observed in children and adolescents.

There were 2 cases of pseudarthrosis of the tibia treated with intramedullary nailing. One of the fractures was near the ankle joint. The fracture site was freshened up and an intramedullary nail was introduced. In one case infection developed and the patient was treated along conservative lines with plaster of Paris casts. In the second case the fracture site was freshened up, the nail introduced and the wound was left open with satisfactory results. The intramedullary nailing was complicated in one case by the fact that the nail broke and in the second case an oversized nail was used. It is important to select the nail very carefully. In case one is in doubt one should choose the thinner nail. The nail should enter the medullary canal about 2 centimeters with each blow. Once the nail was firmly impacted it was almost impossible to remove it. It is better to cut the protruding portion of the nail off once it is impacted instead of trying to remove it *in toto*. The double nail was used in only very few cases. If the nailing was done correctly no additional immobilization was necessary and the results were excellent.

Patients were discharged on the average after 3 1/2 months. There was no muscle atrophy or limitation of motion of the joints. There was one death. One nail in the femur had to be extracted. The nail was so firmly inserted that the greater trochanter had to be chiseled out. The patient developed a generalized infection and died. In 7 cases of compound fractures

of the femur the healing occurred without any complication. In 3 cases complete healing of the soft tissue parts preceded the operation. Intramedullary nailing of the femur was done in 4 cases of tumor and metastases of the bone. Within 10 days the patients were able to walk without any discomfort. The same procedure was also used with good results in osteomyelitis of the femur.

Intramedullary nailing of the humerus was done through the olecranon fossa or through the greater tuberosity. Nailing was done in 10 fractures of the humerus, 2 of which were pseudarthroses, and 1 fracture with metastasis to the humerus. The average hospitalization was 10 days. As a rule there was only a small amount of callus formed along the fracture site.

There were 8 cases of fracture of the radius and ulna which were treated by intramedullary nailing, 16 of which were closed fractures, 3 compound fractures, and 10 pseudarthroses. Some patients resumed heavy work 4 weeks after operation and the nail broke. In nonunion of the ulna and radius, bone grafts from the tibia, ribs and fibula were used in addition to nailing. All of the bones healed satisfactorily. The nailing of the bones of the forearm is the most difficult. In a great many cases the fracture site had to be opened. In only one case was an amputation necessary following introduction of an intramedullary nail, because of widespread chronic osteomyelitis of the entire shaft.

GEORGE L. REIM, M.D.

ORTHOPEDICS IN GENERAL

Hematogenous Osteomyelitis in the Child (Osteomielitis hematogena en el niño) HELMUT W. JAEGER. *Arch. Soc. cir. hep.* Santiago, 1943, Sept. 6, 15.

From January 1943 to June 1947 the author has observed 65 cases of hematogenous osteomyelitis in children of which 35 were acute and 30 were chronic. Eleven of the patients were up to 3 months old, 2 were from 3 months to 2 years old and 53 patients were more than 2 years old. In from 85 to 90 per cent the causal organism was the *Staphylococcus*, generally of the aureus hemolyticus type. Age seemed to be a predisposing factor (below 3 months and between 5 and 15 years) and males were involved two or three times more often than females. The disease has a special predilection for the femur and the tibia. The initial osteomyelitic focus is found in the metaphysis and the diaphysis, but rarely in the epiphysis. At this point the bacteria cause an inflammatory process which develops in the connective tissue of the bone ducts and cavities; the exudate becomes rapidly purulent and spreads gradually following the route of minor resistance. The growth cartilage offers some resistance to the infection, but when this is overcome the epiphysis and the joint may become involved.

The acute process gives rise to a series of changes which acquire their full development in the chronic
